Preface

Nitric oxide (NO) is one of the smallest and simplest of biologically active molecules in nature. Moreover, NO appears to be one of the most ubiquitous substances in mammalian species. As one of the most widespread signaling molecules in the mammal, NO is a major player in controlling nearly every cellular and organ function in the body. NO is the only endogenous molecule that functions as a neurotransmitter, autacoid, constitutive mediator, inducible mediator, cytoprotective molecule, and cytotoxic molecule. Certain physiological functions of NO, such as vasodilation and smooth muscle relaxation, are mediated by multiple mechanisms of NO release and NO action. For example, NO can be released as a neurotransmitter, generated as an autacoid by vascular endothelial cells, or produced by an inducible enzyme. Furthermore, NO can promote biological actions by cyclic GMP-dependent and cyclic GMP-independent molecular mechanisms. Because NO plays multiple physiological roles in regulating numerous and diverse organ functions, defects in the NO pathway lead to the development of many different pathophysiological states. These disorders include hypertension, atherosclerosis, coronary artery disease, cardiac failure, pulmonary hypertension, stroke, impotence, vascular complications in diabetes mellitus, gastrointestinal ulcers, asthma, and other CNS and systemic disorders. It is no surprise, therefore, that nearly all small and large pharmaceutical companies have established research and development programs for discovery of novel therapeutic strategies for NO-based disorders.

The number of annual publications dealing with NO has increased steadily from about 20 in 1986 to over 6000 in 1999. Although numerous reviews, treatises, and books on NO have been published, I felt that there was a need to publish a comprehensive textbook addressing the basic principles of all aspects of the field of NO research. To this end, I presented my thoughts and requests to many investigators

and received overwhelming support to embark on the time-consuming and arduous task of preparing a textbook on NO. The authors of this text are internationally recognized and represent numerous and diverse basic and clinical fields. The challenging task for the authors was to prepare a comprehensive yet terse chapter on the current state of knowledge in the field of their expertise and to write the treatise in an easy, readable textbook style that focuses on principles. One of my tasks was to integrate the chapters to present a unified textbook on the biology and chemistry of NO. I believe that we all succeeded. Our intention has been to make this book an informative resource not only for the basic scientists in the field but also for all clinicians interested or participating in the care of patients with underlying disorders in NO physiology.

This book has 58 chapters that are divided into three major sections that lead from the principles of basic science to clinically applied science. The book begins with an overview of basic principles and then takes us through a more focused view of chemical biology, NO production, NO transport, oxidative stress, and signal transduction mechanisms. The book continues with in-depth coverage of the principles of NO pathobiology in the nervous system, cardiovascular system, and 16 chapters on numerous disease states and pathophysiological disorders involving NO. The final four chapters of the book address important issues on the clinical significance of NO.

Bringing together so many experts from all over the globe was no easy task. I am grateful to the authors, who worked very hard to meet the objectives, and to do so on time. I am also grateful to Dr. Jasna Markovac and to Jenny Wrenn of Academic Press, without whose continuous support this project would have never been launched or completed.

Louis J. Ignarro

Introduction and Overview

Historical Perspectives

Nitroglycerin has been used clinically for well over 100 years to treat angina pectoris but only recently has its mechanism of action been elucidated and attributed to nitric oxide (NO) and cyclic GMP (cGMP). The field of cGMP research preceded the field of NO research. Long before the first significant biological experiments with NO were conducted, the presence of cGMP in mammalian urine was reported, and this led to a widespread interest in the possible biological roles of this new cyclic nucleotide. Up until 1969, cyclic AMP (cAMP) was the only cyclic nucleotide known to play important biological roles in cellular function. In 1969, however, cGMP was detected in mammalian tissues and guanylate cyclase was first discovered and partially characterized. Guanylate cyclase catalyzes the conversion of GTP to cGMP plus inorganic pyrophosphate in a reaction that requires a divalent metal cation such as magnesium. The first insight into the possible importance of endogenous cGMP in biological function was the finding that the decrease in cardiac contractility mediated by acetylcholine is associated with a concomitant and rapid accumulation of cardiac cGMP. Much of the early work involving cGMP suggested that it might function to mediate or signal cellular processes that are ultimately antagonistic or opposite in direction to those mediated by cAMP. This yin–yang hypothesis of biological control signified a type of control mechanism mediated through dual, opposing actions of cGMP and cAMP in bidirectionally regulated systems. Some of the best examples of the dualism theory of biological control were provided by studies on circulating cells such as neutrophils, lymphocytes, and macrophages and on related cells such as mast cells. In general, increases in cGMP production were associated

with stimulation of cell function such as phagocytosis and discharge of lysosomal enzymes, whereas increases in cAMP production were associated with inhibition of these functions.

Research involving cGMP was well under way before the connection between NO and cGMP was made in the mid to late 1970s. Before this time, cAMP was believed to mediate the smooth muscle relaxant responses to certain catecholamines, prostaglandins, and adenosine, whereas there was no link between cGMP and smooth muscle function. The first clue that cGMP might be involved in smooth muscle relaxation was discovered in 1975, when sodium azide, hydroxylamine, and sodium nitrite, which were known to be smooth muscle relaxants, were reported to elevate tissue levels of cGMP and to activate guanylate cyclase. Subsequently, nitroglycerin was shown to elevate cGMP levels in rat myometrium and canine femoral artery, and sodium nitroprusside was demonstrated to increase cGMP levels in rat ductus deferens independently of calcium. An important report then appeared showing that nitroglycerin, sodium nitroprusside, and other nitro compounds increased cGMP levels in bovine tracheal smooth muscle, and this was associated with smooth muscle relaxation. Other reports appeared confirming these novel early observations and supporting the hypothesis that cGMP might be involved in mediating smooth muscle relaxation.

Prior to the evidence that cGMP might be involved in smooth muscle relaxation, cGMP was implicated in smooth muscle contraction. Numerous diverse chemical agents elevated cGMP levels in a calcium-dependent manner in smooth muscle tissues, which also contracted in response to such added agents. Additional experiments revealed that there was no direct relationship between smooth muscle

contraction and cGMP accumulation and that inhibition of cGMP accumulation actually enhanced contractile responses. Therefore, experimental evidence for any physiological role of cGMP in smooth muscle function was controversial. These latter observations were actually consistent with the developing hypothesis that cGMP may be associated with smooth muscle relaxation. The earlier studies showing that nitro compounds stimulated cGMP accumulation in and relaxation of smooth muscle tissues suggested that NO might somehow be involved because certain nitro compounds were known to decompose to NO. The first experiments showing that NO directly relaxes vascular smooth muscle came in 1979, and relaxation was associated with guanylate cyclase activation and cGMP formation. Added chemical analogs of cGMP also caused vascular smooth muscle relaxation. NO gas caused a transient but concentration-dependent relaxation of isolated strips of bovine coronary artery that was blocked by added hemoproteins or methylene blue. Other nitro compounds, including nitrosoamines that generate NO, were shown to elicit similar effects on vascular smooth muscle. Even tobacco smoke, which contains approximately 800 ppm of NO gas, activated guanylate cyclase and caused vascular smooth muscle relaxation. These *in vitro* effects were not artifacts of *in vitro* isolated preparations, as marked hypotensive responses were also observed *in vivo*.

The unequivocal demonstration that nitrovasodilators elicit vascular smooth muscle relaxation via the actions of NO came in 1981, when organic nitrate and nitrite esters, inorganic nitroso compounds, and nitrosoamines were shown to react with thiols to form intermediate S-nitrosothiols, which were unstable and decomposed with the liberation of NO. The liberated NO then activated guanylate cyclase and elevated smooth muscle levels of cGMP, resulting in smooth muscle relaxation. A series of S-nitrosothiols were synthesized and found to be excellent NO donor molecules both *in vitro* and *in vivo*. The S-nitrosothiols, first described in 1980, represented the first known biologically active NO donor agents.

At about the time that the nitrovasodilators were shown to work via a NO mechanism, NO was first shown to inhibit platelet aggregation. Both the initial observation in the laboratory that sodium nitroprusside inhibited platelet aggregation and the obvious question of whether NO could be responsible for this action of sodium nitroprusside prompted this study. NO and other NO donor agents all inhibited platelet aggregation via NO and cGMP-dependent mechanisms.

As evidence that NO stimulated cGMP production, promoted smooth muscle relaxation, and inhibited platelet aggregation accumulated, studies were under way to elucidate the mechanism by which NO activates guanylate cyclase. Earlier studies with relatively crude preparations of soluble guanylate cyclase suggested, and subsequent studies with purified enzyme demonstrated, that heme is required for activation of soluble guanylate cyclase by NO and nitro compounds that generate NO. NO reacts with reduced heme iron, bound as a prosthetic group on guanylate cyclase, to form

the nitrosyl-heme adduct, resulting in enzyme activation. The activation of guanylate cyclase occurs as a 100- to 200-fold increase in the V_{\max} and a three- to four-fold decrease in the K_m for MgGTP substrate. Enzyme activation by NO can be blocked by hemoglobin or myoglobin by virtue of the capacity of hemoproteins to compete with guanylate cyclase for NO. Oxyhemoproteins can catalyze the rapid oxidation of NO to nitrate anion (NO_3^-) before the NO binds to the guanylate cyclase and thereby prevent enzyme activation.

The discovery of endothelium-dependent vascular smooth muscle relaxation and endothelium-derived relaxing factor (EDRF) occurred just as investigators were elucidating the mechanism of action of nitrovasodilators and the mechanism by which NO activates guanylate cyclase. The identification of EDRF took about 6 years after its initial discovery in 1980. The early experiments concerned with the identification of EDRF were varied in design and led to different conclusions, none of which indicating that EDRF might be NO. Suggestions ranged from arachidonic acid metabolites to carbonyl compounds. In 1984, we reported that methylene blue inhibits the capacity of acetylcholine (EDRF) to stimulate vascular cGMP production and also inhibits endothelium-dependent relaxation. Methylene blue was shown earlier to inhibit the capacity of NO to stimulate vascular cGMP production and, therefore, also relaxation. These observations suggested that EDRF closely resembles NO, but this conclusion was not drawn in our original publication in 1984. It became obvious to us soon after the publication of these data that EDRF might very well be NO. Experiments were designed to ascertain whether EDRF, like NO, could activate cytosolic guanylate cyclase. Bovine arterial or venous rings with intact endothelium were individually incubated in small test tubes containing purified soluble guanylate cyclase, and acetylcholine, bradykinin, or calcium ionophore was added to the reaction mixtures. The result was activation of the purified soluble guanylate cyclase. Endothelium-denuded rings did not liberate a factor that activated guanylate cyclase. Addition of methylene blue or hemoglobin blocked the activation of guanylate cyclase. These studies suggested that EDRF from artery and vein liberate NO, although this conclusion was omitted from the paper, pending additional evidence that EDRF is NO.

The next experiment, which was more selective than the former, revealed for the first time that EDRF might be NO. This experiment was essentially the same as that described above except that two forms of soluble guanylate cyclase were used. One form was the native heme-containing guanylate cyclase and the other form was heme-deficient enzyme. Only the heme-containing form of guanylate cyclase was activated by the endothelium-derived factors released from artery and vein by the endothelium-dependent vasorelaxants. The most definitive experiment that we conducted, showing that EDRF is NO, came from a spectral assay designed to determine whether the EDRF released from isolated fresh bovine aortic endothelial cells could mimic NO in its reaction with deoxyhemoglobin to form the characteristic nitrosyl-heme adduct of hemoglobin. NO characteristically

reacts with deoxyhemoglobin to cause a leftward shift in the Soret absorption maximum from 433 to 406 nm. Only NO causes this characteristic shift in spectrum. When the untreated endothelial cells were mixed with the endothelial cells, no change in spectrum was observed. However, when calcium ionophore was added to the mixture of endothelial cells and deoxyhemoglobin, a shift in the Soret absorption maximum from 433 to 406 nm promptly occurred, thereby indicating that EDRF was NO.

The discovery that EDRF is NO triggered an avalanche of independent studies by hundreds of different investigators in many diverse directions. The discovery implicated that vascular endothelial cells can synthesize NO from some unknown precursor linked to an interaction between a calcium ionophore and the endothelial cell membrane. This is all that was known before arginine was discovered as the substrate for the synthetic reaction and NO synthase was discovered as the enzyme system responsible for the conversion of arginine to NO.

Mechanism of Action of Nitrovasodilators

The mechanism of vasodilator action of nitroglycerin and other organic nitrate esters remained completely unknown from its first clinical use in the 1870s until 1981. The earliest mechanistic studies on nitroglycerin in the 1970s, conducted by Needleman and colleagues, revealed that persistent administration of high doses of drug to animals resulted in the development of tolerance, which was correlated with gradual depletion of tissue thiols. After additional experiments, the authors concluded that nitroglycerin required the presence of free thiol sulfhydryl groups in order to relax vascular smooth muscle. They thought that certain critical “thiol receptors” were required for interaction with nitroglycerin to cause vasorelaxation and that repeated exposure to nitroglycerin somehow caused depletion of these critical thiols.

Murad and colleagues discovered that nitroglycerin and other nitro compounds were activators of guanylate cyclase and could stimulate cGMP formation in tissues including smooth muscle. When we repeated similar experiments, we noted that nitroglycerin was only a weak activator of guanylate cyclase but that the addition of thiols such as cysteine to enzyme reaction mixtures markedly enhanced enzyme activation by nitroglycerin. Moreover, we found that thiols enhanced the capacity of various nitro compounds to activate guanylate cyclase and that nitroglycerin specifically required the presence of cysteine to cause enzyme activation. These observations began to reveal some similarities to those earlier experiments conducted by Needleman’s group. Not only were thiols required for sustained vasorelaxation, but thiols were also required for activation of guanylate cyclase by nitroglycerin and related organic nitrate esters. What was the connection? Subsequent experiments revealed that the nitro compounds including nitroglycerin reacted with thiols to form intermediate *S*-nitrosothiols, which were chemically unstable and could be readily converted to NO under various

conditions. These observations explained why tolerance readily develops to nitroglycerin but not to other nitrovasodilators. Repeated administration of nitroglycerin causes thiol depletion by utilizing all the stores of available thiol to generate *S*-nitrosothiol. In the absence of thiol, there can be no formation of *S*-nitrosothiol and, therefore, NO. Other nitrovasodilators do not absolutely require the presence of free thiol in order to liberate NO, although added thiol can enhance liberation of NO. The conclusion from these experiments was that thiols facilitate the activation of soluble guanylate cyclase by nitrovasodilators via mechanisms that involve liberation of NO from the parent molecules. Figure 1 is a schematic illustration of the mechanism of action of various nitrovasodilators.

Based on these studies, a series of *S*-nitrosothiols were synthesized and found to be good NO donor agents both *in vitro* and *in vivo*. Two of these, *S*-nitroso-*N*-acetylpenicillamine (SNAP) and *S*-nitrosoglutathione (GSNO), have become popular NO donor agents in the laboratory. These two *S*-nitrosothiols are relatively stable in the solid form but decompose readily in aqueous solution. Perhaps more importantly, *S*-nitrosothiols can liberate NO much faster in the presence of tissue or biological components such as cations, heme iron, and thiol-containing proteins. For example, the nitroso moiety of an *S*-nitrosothiol readily undergoes transfer

Figure 1 Schematic illustration of mechanism of vascular smooth muscle relaxant action of nitrovasodilators. Organic nitrate esters such as nitroglycerin ($R-ONO_2$) and organic nitrite esters such as isoamyl nitrite ($R-ONO$) permeate cells and react with thiols ($R-SH$) to form intermediate *S*-nitrosothiols ($R-SNO$) plus the corresponding alcohol ($R-OH$). $R-SNO$ decomposes, especially in the presence of copper (Cu^+), to form nitric oxide (NO). Nitroprusside ($R-FeNO$) is an inorganic molecule that does not permeate cell membranes but undergoes decomposition to yield NO , which is lipophilic and readily enters cells. $R-NO_x$ represents other types of NO donor molecules that may or may not enter cells but decompose to yield NO . NO activates cytosolic guanylate cyclase (G cyclase), which catalyzes the conversion of GTP to $cGMP$ plus inorganic pyrophosphate (PP_i) in the presence of magnesium (Mg^{2+}). $cGMP$ promotes the activation of a protein kinase (G kinase), resulting in the phosphorylation of several proteins, which in turn leads to vascular smooth muscle relaxation.

to other molecules like proteins that contain free sulfhydryl groups. This transnitrosation reaction is relatively rapid and may be biologically important in the transport and actions of NO.

Antiplatelet Action of NO

By the mid 1970s it was known that endothelial denudation leads to rapid platelet adhesion, aggregation, degranulation, and recruitment of additional platelets that ultimately result in thrombus formation. Platelets aggregate in response to a number of agents, such as ADP, epinephrine, serotonin, thrombin, vasopressin, arachidonic acid metabolites, subendothelial matrix components, immune complexes, viruses, and bacteria. Platelet aggregation includes two phases: (1) a primary reversible phase, during which the discoid platelets change their shape and adhere to the exposed subendothelial tissue, and (2) a second, irreversible phase, which causes platelet secretion, release of platelet components, and recruitment of additional platelets. Patients suffering from cardiovascular and cerebrovascular disorders have an increased susceptibility to platelet aggregation, and factors such as dietary lipids, smoking, and stress appear to alter normal platelet aggregation. By the late 1970s the role of cAMP in platelet function was well established, but that of cGMP was uncertain. A number of contradictory reports showed that arachidonic acid metabolites, serotonin, ADP, or collagen caused an increase in platelet cGMP levels. One important observation made at that time was the fact that cAMP elevation inhibited both platelet aggregation and degranulation, whereas cGMP accumulation was associated only with inhibition of platelet aggregation. At the same time it was reported that sodium nitroprusside and nitroglycerin produced accumulation of cGMP in vascular and nonvascular smooth muscle cells. Other studies indicated the ability of sodium nitroprusside and nitroglycerin to inhibit platelet aggregation by a mechanism that was unrelated to cAMP accumulation.

The first report that correlated the antiaggregatory effects of NO, sodium nitroprusside, *N*-methyl-*N'*-nitro-*N*-nitrosoguanidine, and cigarette smoke with the inhibitory role of guanylate cyclase activation and cGMP accumulation in platelets was published in 1981. All the discordant and contradictory information up to that time was explained. The authors also showed that NO and the nitro compounds disaggregated the platelets already aggregated by ADP and that this effect was mediated by cGMP. In addition to NO, antiaggregatory effects were also found with 8-bromo-cGMP (more lipophilic analog of cGMP) and relatively selective inhibitors of cGMP phosphodiesterase. To further confirm the involvement of the NO–cGMP signal transduction pathway in the inhibition of platelet aggregation by nitro compounds, the authors used hemoproteins to inactivate NO, and this abolished the antiaggregatory effects. A series of *S*-nitrosothiols, all potent activators of guanylate cyclase, showed a marked elevation of platelet cGMP levels that was correlated with the inhibition of platelet aggregation. In a

study published in 1983, the same authors used synthetic *S*-nitrosothiols to show their heme-dependent activating effects on a partially purified soluble fraction of guanylate cyclase from human platelets.

By the mid 1980s it was already known that platelet activation played an important role in atherosclerosis, but most of the attention in clinical research was directed toward the cAMP elevating agents that inhibited platelet aggregation. In 1986, when EDRF was identified as NO, a timely shift took place in viewing the importance of NO in vascular disorders. In addition to NO, prostaglandin I₂ (prostacyclin) is another endothelium-derived vasodilator that also inhibits platelet aggregation. However, NO, but not prostacyclin, also inhibits platelet adhesion to the intimal lining of blood vessels. The platelet antiaggregatory effect of prostacyclin is mediated by cAMP. Therefore, at least two distinct, endothelium-derived, signal transduction pathways function to inhibit platelet function and thrombosis. The distinction between these two pathways, however, may be more apparent than real. For example, there may be a close regulatory link between NO and cAMP. NO can activate cyclooxygenase by cGMP-independent mechanisms and thereby enhance the production of prostacyclin, which acts via cAMP. This action of NO to stimulate cAMP production may account for the synergistic effects of NO and prostacyclin on platelet function. Thus, the loss of both endothelial products that regulate normal blood flow in vascular disorders, such as atherosclerosis and ischemia–reperfusion injury, will have profound pathophysiological consequences. This further underlies the importance of the clinical use of NO donors to restore vascular and platelet function in disorders involving endothelial dysfunction.

Red blood cells apparently contribute to vascular and platelet homeostasis in a new and unexpected manner. Red blood cells have been shown to contain a cytosolic, constitutive, calcium-dependent endothelium type of NO synthase. Human and rat red blood cells are capable of inhibiting platelet aggregation and degranulation. This effect is prevented by preincubation of red blood cells with NO synthase inhibitors, indicating that NO released from red blood cells plays a role in the antiplatelet action of red blood cells. The contribution of plasma, blood cellular components, and blood vessels to the available pool of NO reveals the complexity of the biological and chemical microenvironment that ultimately determines platelet function.

NO acts in an autocrine or paracrine manner to modulate platelet function via cGMP-dependent and cGMP-independent mechanisms. In the first case, cGMP carries out its effects by targeting three types of effector molecules: (1) cGMP-dependent protein kinases, (2) cGMP-gated cation channels, and (3) phosphodiesterases. cGMP-dependent protein kinases are the primary mediators of cGMP inhibitory action on platelet aggregation. They act by inhibiting agonist-elicited elevation of intracellular Ca²⁺ by blocking the formation of phospholipase C-mediated inositol 1,4,5-trisphosphate (IP₃), a Ca²⁺-mobilizing intracellular messenger, from membrane phospholipids. In platelets, the

Ca^{2+} -regulating action of cGMP-dependent protein kinases is mimicked by cAMP-dependent protein kinases. Cytoskeleton-associated, vasodilator-stimulated phosphoprotein (VASP), a modulator of P-selectin and the GP IIb–IIIa complex involved in platelet adhesion and recruitment, appears to be the common target for both cGMP- and cAMP-dependent protein kinases. cGMP-gated ion channels belong to the cyclic nucleotide-gated ion channel family. Allosteric interaction of cGMP with cation channels has been documented in a number of cell types and may also inhibit platelet activity. Phosphodiesterases are enzymes that hydrolyze and inactivate cGMP and cAMP. cGMP can utilize the cAMP pathway by binding to and inhibiting specific phosphodiesterases to modulate cellular cAMP levels and thus affect platelet function. Two of the nine phosphodiesterases currently known, phosphodiesterase II and phosphodiesterase III, are regulated by cGMP. Phosphodiesterase III, which is present in platelets and hydrolyzes cAMP, is inhibited by cGMP in a process that results in intraplatelet accumulation of cAMP and inhibition of platelet aggregation.

There may also be cGMP-independent regulatory effects of NO on platelet function. Cyclooxygenase activation by NO causes cAMP-mediated antiplatelet effects, as discussed above. Other mechanisms, such as NO-mediated inhibition of cytochrome P-450 (responsible for metabolism of a variety of molecules including prostaglandins) and modulation of intracellular iron status are possible. Under pathophysiological conditions, NO may produce nitrosative and oxidative stress, resulting in reduction of intracellular thiols and inactivation of membrane receptors, ion transporters, and key metabolic enzymes, all of which can alter platelet and vascular functions. Platelets, just other cell types, are influenced by NO in a complex manner, and awareness of the multiple mechanisms of action of NO in physiology and pathophysiology is important.

Mechanism of Guanylate Cyclase Activation by NO

As discussed above, NO was discovered to activate the soluble isoform of guanylate cyclase in the mid 1970s, al-

though the mechanism was not understood. In the absence of NO, guanylate cyclase still displayed catalytic activity in converting GTP to cGMP plus inorganic pyrophosphate (Fig. 2). The K_m for MgGTP substrate (or GTP in the presence of excess magnesium), is approximately $100\ \mu\text{M}$ and the V_{\max} of the enzymatic reaction is approximately $0.1\ \mu\text{mol}/\text{min}/\text{mg}$ enzyme protein. Addition of NO to enzyme reaction mixtures lowers the K_m for MgGTP from 100 to about $30\ \mu\text{M}$ and increases the V_{\max} from 0.1 to about 10 to $20\ \mu\text{mol}/\text{min}/\text{mg}$ enzyme protein. This represents about a threefold increase in the apparent affinity of guanylate cyclase for MgGTP substrate and a 100- to 200-fold increase in V_{\max} or specific activity of guanylate cyclase.

Several studies in the late 1970s suggested that heme might be necessary for NO to activate guanylate cyclase. This hypothesis was based on some interesting experiments showing that the addition of heme or hemoglobin to relatively crude tissue preparations containing guanylate cyclase resulted in greater enzyme activation by NO and nitro compounds thought to liberate NO. These observations suggested that heme might be a bound component such as a prosthetic group on guanylate cyclase, which served to attract and bind NO to allow it to activate guanylate cyclase. Accordingly, two laboratories set out to ascertain whether or not soluble guanylate cyclase was a hemoprotein that could bind NO. The results clearly indicated that soluble guanylate cyclase purified from bovine lung contained stoichiometric quantities of bound heme. In other experiments, it was possible to detach the heme from guanylate cyclase without denaturing the enzyme protein or decreasing its basal catalytic activity. Such heme-deficient guanylate cyclase preparations failed to undergo activation in the presence of added NO. However, addition of heme or hemoglobin back to enzyme reaction mixtures completely restored the capacity of NO to activate the enzyme. The heme-deficient enzyme could be readily and easily reconstituted with heme by incubation of enzyme with heme or hematin under mild reducing conditions ($2\ \text{mM}$ dithiothreitol) at 37°C for 20 min. Heme-reconstituted guanylate cyclase behaved just like native enzyme with respect to activation by NO.

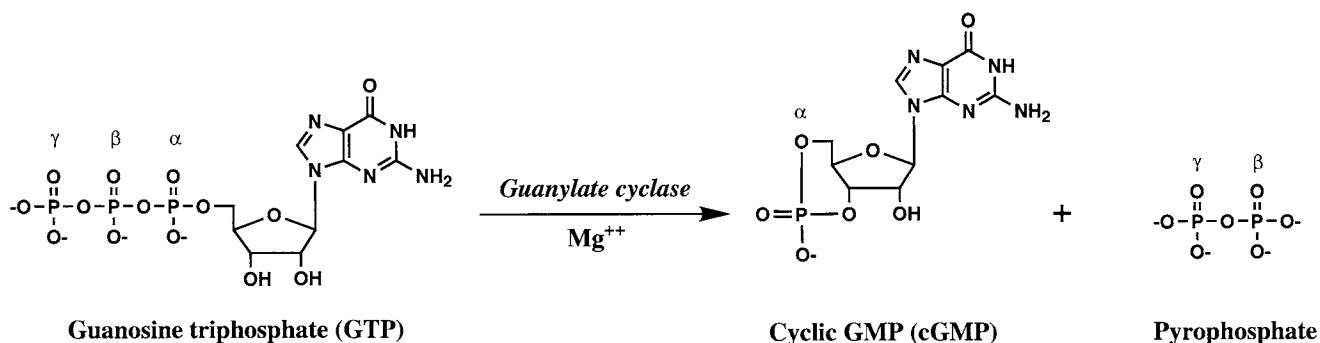

Figure 2 Guanylate cyclase enzymatic reaction. Guanylate cyclase catalyzes the conversion of guanosine 5'-triphosphate (GTP) to cyclic guanosine 3',5'-monophosphate (cyclic GMP) plus inorganic pyrophosphate. The terminal two phosphate groups (β and γ) are cleaved as pyrophosphate, and the α phosphate cyclizes to the 3' position on the ribose yielding cyclic GMP.

These studies indicated that soluble guanylate cyclase contains heme and provided the basis for arguing that guanylate cyclase contains a high affinity binding site for NO. Indeed, the heme iron of guanylate cyclase can be regarded as the intracellular receptor site for NO. The question of mechanism of activation of guanylate cyclase by NO still remained. What occurs after NO binds to the heme iron on guanylate cyclase? In order to address this critical mechanistic question, we examined the role of the heme iron itself in enzyme activation by NO. Accordingly, protoporphyrin IX, which is essentially heme without iron, was tested for its binding affinity for purified guanylate cyclase. When protoporphyrin IX was mixed with heme-deficient guanylate cyclase and subsequently chromatographed on a gel filtration column to remove all traces of unbound protoporphyrin IX, some of the porphyrin remained bound to the guanylate cyclase, as determined by spectral analysis. Interestingly, the porphyrin-bound guanylate cyclase recovered from the column was found to be in the fully activated state. That is, its catalytic activity resembled that found on addition of NO to heme-containing guanylate cyclase. Subsequent experiments revealed consistently that protoporphyrin IX activates heme-deficient guanylate cyclase and even heme-containing enzyme by mechanisms involving the displacement of enzyme-bound heme and its replacement with protoporphyrin IX.

A series of enzyme kinetic experiments revealed that protoporphyrin IX activates guanylate cyclase by mechanisms that could not be distinguished from the mechanisms by which NO causes enzyme activation. Protoporphyrin IX was capable of activating either heme-containing or heme-deficient guanylate cyclase, whereas NO required the absolute presence of heme to cause enzyme activation. When the nitrosyl-heme complex itself was prepared and added to enzyme reaction mixtures, we noted that, like protoporphyrin IX, nitrosyl-heme activated both heme-deficient and heme-containing preparations of guanylate cyclase. These observations prompted an in-depth comparative analysis of the kinetic mechanisms by which protoporphyrin IX and nitrosyl-heme activate guanylate cyclase. The results of the experiments revealed that identical mechanisms were involved in guanylate cyclase activation by protoporphyrin IX and nitrosyl-heme. After considerable thought and reflection, we proposed a mechanism that might explain these observations and, therefore, how NO might activate guanylate cyclase. This mechanism is illustrated schematically in Fig. 3. In essence, the hypothesis is that the binding of NO to enzyme-bound heme iron causes a conformational change in the metalloporphyrin attributed to cleavage of the axial ligand between the iron and the enzyme protein. The maintenance of five-coordinate chemistry before and after NO binding indicates that the axial ligand must break. If the process in guanylate cyclase is similar to that in hemoglobin, the heme iron will protrude out of the planar porphyrin ring configuration and expose the underlying region of the protein. The hypothesis is based on the speculation that the catalytic site for MgGTP binding in guanylate cyclase lies in

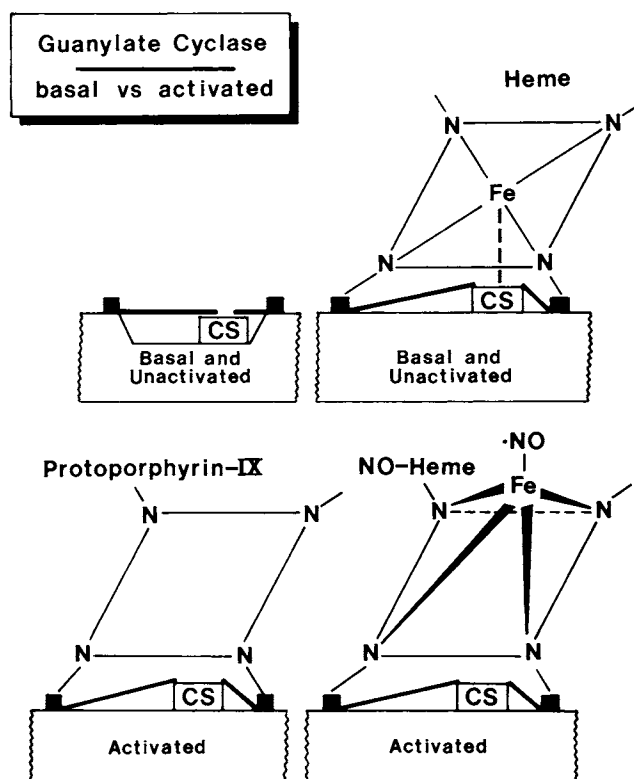

Figure 3 Mechanism of activation of guanylate cyclase by NO. The native enzyme contains bound heme as a five-coordinate complex. The heme iron is coordinated to each of the four pyrrole nitrogen atoms and forms an axial ligand with a histidine residue in the enzyme protein. The heme or porphyrin binding site is hypothesized to be adjacent to the substrate binding site or catalytic site (CS). Binding of heme to guanylate cyclase may cause a conformational change at the substrate binding site, resulting in exposure of the catalytic site to the external environment containing the substrate. The axial ligand, however, may sterically interfere with substrate binding, allowing only a slow catalytic rate. This is designated as basal or resting activity and the enzyme is in the unactivated state. Detachment of heme from guanylate cyclase does not cause any appreciable change in catalytic activity. NO binds to the heme iron to form the nitrosyl-heme or NO-heme complex. The NO-heme complex remains five-coordinate, signifying that the original axial ligand is severed, allowing the iron to protrude outward away from the plane of the porphyrin ring structure. The hypothesis is that such exposure of the catalytic site (CS) allows more efficient substrate binding and a markedly increased catalytic rate. Protoporphyrin IX activates guanylate cyclase by a similar mechanism. Porphyrin binding, whether by protoporphyrin IX or heme, may cause a similar conformational change at the substrate binding site, resulting in exposure of the catalytic site to substrate. Since there is no iron in protoporphyrin IX, there is no axial ligand to sterically interfere with substrate binding. Therefore, binding of protoporphyrin IX causes enzyme activation by increasing exposure of the catalytic site to substrate. This is essentially the same mechanism by which NO-heme causes activation of guanylate cyclase.

close proximity to the site of axial ligand interaction. When heme is bound to guanylate cyclase, the axial ligand inflicts steric hindrance to the binding of substrate and accounts for the relatively low basal catalytic activity. When NO binds to heme iron, however, breakage of the axial ligand and consequent exposure of the catalytic site to more substrate results in a markedly increased catalytic rate (greater V_{\max}). The fa-

cilitation of substrate binding probably accounts for the lower K_m value observed for the activated enzyme.

The previous observations have been confirmed by several investigators. The actual heme content of soluble guanylate cyclase is debatable, with different investigators reporting anywhere from less than 1 to 1.5 mol of heme per mole of the heterodimeric enzyme. This debate will be settled when the crystal structure of the enzyme is obtained. The fact that protoporphyrin IX causes heme-independent activation of guanylate cyclase by kinetic mechanisms indistinguishable from those of the nitrosyl-heme complex helped in the elucidation of the mechanism by which NO activates guanylate cyclase. In the unactivated state, the heme of guanylate cyclase is five-coordinate with the histidine-105 of the β subunit bound to the fifth coordination position of the heme iron. This species has an absorption maximum at 430 nm. NO binds to the sixth coordination position of heme. However, the heme still remains five-coordinate because in the process of NO binding, the histidine to iron coordinate bond breaks. This species has an absorption maximum at 398 nm. It is thought that this loss of histidine-iron bond facilitates the interaction of the porphyrin portion of the complex with the enzyme to cause activation. The association of NO to a five-coordinate iron is known to be nearly diffusion controlled. The dissociation of NO from the complex is also rapid when compared to other hemoproteins. Moreover, NO dissociation increases by about 40- to 50-fold in the presence of the substrate MgGTP, giving a half-life for the nitrosyl adduct of about 5 s at 37°C. This half-life is probably fast enough for rapid deactivation of guanylate cyclase in biological systems.

Copper may also be bound to soluble guanylate cyclase under physiological conditions. The role of the copper is unknown but one possibility might be to facilitate the activation of guanylate cyclase by endogenous *S*-nitrosothiols. Copper (Cu^+) catalyzes the decomposition of *S*-nitrosothiols with the liberation of NO. This might be the mechanism by which *S*-nitrosothiols activate guanylate cyclase by kinetic mechanisms that closely resemble those for NO. Moreover, this would be a convenient mechanism to allow both free NO and *S*-nitrosothiols to activate guanylate cyclase similarly.

Biosynthesis of NO

The recognition of NO as a signaling molecule, the biosynthesis of NO and its regulation, and subsequent cloning and characterization of the enzymes responsible for its production stem from three separate but merging lines of investigation. The search for the endogenous vasodilator agent produced by the vascular endothelium, the investigations into the mechanisms of excitatory neurotransmission, and the cytotoxic actions of macrophages would all converge on NO. Research into the vascular actions of NO began with an apparent experimental paradox. Despite the potent vasodilating action of acetylcholine (ACh) *in vivo*, it did not always

produce relaxation of isolated preparations of blood vessels *in vitro*. For example, in helical strip preparations from rabbit thoracic aorta, ACh at relatively high concentrations caused contractions. This contractile effect was mediated by muscarinic receptors. It was observed that if a ring preparation was made, ACh produced marked relaxation at concentrations much lower than those required to produce contraction in the helical strip preparation. It was discovered that the loss of relaxation caused by ACh in the helical strip was the result of unintentional rubbing of its intimal surface during its preparation. If the intimal surface was preserved during preparation, the tissue, whether ring or strip, always exhibited relaxation to ACh. This implied a role for endothelial cells, found in the intimal surface. ACh, acting on muscarinic receptors of the endothelium, stimulates the release of EDRF, which causes relaxation of the vascular smooth muscle. Like ACh, bradykinin was also known to elicit the relaxation of certain isolated arterial rings. Following the example set by acetylcholine, researchers discovered that after removing the endothelial cells from the vessel wall by rubbing the intimal surface, canine arteries failed to relax upon the addition of bradykinin. As with rabbit thoracic aorta, endothelial cells of canine arteries stimulated with bradykinin appeared to release a substance mediating vascular smooth muscle relaxation. Several other substances were found to elicit the release of EDRF from the endothelium and cause subsequent relaxation in specific vascular tissues from different animals. These elicitors included ACh, bradykinin, the calcium ionophore A23187, ATP and ADP, substance P, bradykinin, histamine mediated by H_1 -receptors, thrombin, serotonin, and norepinephrine mediated by α_2 receptors.

After the identification of EDRF as NO, studies revealed that histamine, ACh, bradykinin, and the calcium ionophore A23187 all enhanced NO release from endothelial cells perfused with L-, but not D-arginine. The release of ^{15}NO , from L-[*guanido*- $^{15}\text{N}_2$]arginine was determined by mass spectrometry, indicating that NO was formed from one of the chemically equivalent guanidino nitrogens of L-arginine. The inhibitor, L- N^G -methylarginine, but not D- N^G -methylarginine, inhibited the generation of NO by endothelial cells in culture. Both of these effects were reversed by the addition of excess L-arginine. These data indicated that L-arginine is the precursor for the formation of NO by vascular endothelium.

In the central nervous system (CNS), activity in excitatory pathways is correlated with subsequent increases in the levels of cGMP. Accordingly, exogenous stimulation of the brain with the excitatory neurotransmitter, glutamate, was found to cause a striking increase in cGMP levels in brain tissue. Brain tissue was found to contain an endogenous activator of guanylate cyclase activity. This activator was both acid soluble and removed by cation-exchange chromatography, suggesting a basic compound. The activator was then purified from rat brain and identified as L-arginine by ^{13}C - and ^1H -NMR spectroscopy and by paper chromatography. L-Arginine, at a concentration of 10–20 μM , stimulated guanylate cyclase activity 15- to 25-fold, whereas D-arginine

and other basic L-amino acids were ineffective. The authors suggested that the activation of neuronal guanylate cyclase by L-arginine was similar to earlier reports that guanylate cyclase is activated by nitroso compounds. Not until several years later would the assumption that arginine could function as a direct activator of guanylate cyclase be disproved. Arginine failed to activate purified guanylate cyclase.

As an excitatory neurotransmitter, glutamate functions through both ionotropic (*N*-methyl-D-aspartate, NMDA) and metabotropic (kainate) receptors. The activation of NMDA receptors in rat cerebellum leads to the release of EDRF, by this time identified as NO, a direct activator of guanylate cyclase. L-Arginine, but not D-arginine, augmented the response to NMDA. The results indicated that stimulation of NMDA receptors results in the activation of an enzyme that catalyzes the formation of NO from L-arginine. Similar results were found with the activation of kainate receptors in rat cerebellum. The response in slices was Ca^{2+} dependent, augmented by L-arginine, and reversibly inhibited by L-*N*^G-methylarginine. It was concluded that stimulation of kainate receptors also leads to activation of an enzyme that synthesizes NO from L-arginine and that activation of soluble guanylate cyclase by the released NO accounts for cGMP generation.

While researchers were elucidating the role of NO biosynthesis in vascular endothelium and studying glutamate signaling in the brain, others were following a different line of investigation that would also lead to NO. It was observed that both humans and germfree rats excreted more nitrate than was ingested, suggesting endogenous biosynthesis of nitrate. The generation of nitrate increased significantly in infected animals, but it was difficult to exclude a possible role for the infectious agent in producing the observed increase in nitrate levels. This problem was simplified when it was reported that injection of an immunogenic bacterial cell wall constituent, lipopolysaccharide (LPS), could induce nitrate biosynthesis. Thus, intraperitoneal injection of LPS led to a transient increase in nitrate levels in blood and urine. Furthermore, peritoneal macrophages cultured from susceptible mice produced nitrite and nitrate when cultured with LPS, implicating the immune system in the observed phenomenon. LPS-induced nitrate synthesis was also observed with nude mice, indicating that neither functional T lymphocytes nor LPS-responsive B lymphocytes were required for the response *in vivo*. This suggested that macrophages were responding to LPS independent of other immune cells. The researchers responsible for this discovery suggested that nitrite synthesis is significant because of its potential involvement in the chemistry of macrophage-mediated cytotoxicity. They confirmed their own suspicions a few years later while investigating the RAW 264.7 macrophage cell line. When activated by LPS plus interferon- γ (IFN- γ) these cells synthesized high levels of nitrite (NO_2^-) and nitrate (NO_3^-). Changing the medium after activation enabled them to show that L-arginine was the only amino acid essential for this synthesis. Also, the stereoisomer D-arginine would not substitute for L-arginine. When morpholine (tetrahydro-1,4-oxazine) was added to the culture medium of the activated

macrophages, N-nitrosation occurred, generating *N*-nitrosomorpholine. Gas chromatography–mass spectrometry (GC/MS) experiments using L-[*guanido*- $^{15}\text{N}_2$]arginine established that both NO_2^- and NO_3^- and the nitrosyl group of *N*-nitrosomorpholine were derived exclusively from one of the chemically equivalent guanidino nitrogens of arginine. Chromatographic analysis showed that the other product in the conversion of L-arginine to NO_2^- and NO_3^- was L-citrulline. The enzymatic conversion of L-arginine to L-citrulline plus NO_2^- and NO_3^- is oxidative but was found to require reducing equivalents in the form of NADPH. When subcellular fractions containing the enzyme activity were incubated with L-arginine and NADPH, transient generation of NO was observed. As with other experiments, the formation of NO_2^- and NO_3^- was inhibited by L-*N*^G-methylarginine, but so was the generation of NO, suggesting that NO is an intermediate in the biosynthesis of NO_2^- and NO_3^- . Furthermore, when incubated with L-[*guanido*- $^{15}\text{N}_2$]arginine, NO was ^{15}N -labeled. The results clearly demonstrated that NO is an intermediate in the conversion of L-arginine to NO_2^- , NO_3^- , and citrulline.

Once established that NO was endogenously produced in vascular endothelium, brain, and the immune system, the quest to isolate the responsible enzyme and to characterize its properties was under way. Early attempts to isolate NO synthase were problematic due to the difficulty in monitoring the generation of a transient species such as NO. This problem was averted when investigators followed the stoichiometric conversion of L-arginine to L-citrulline that accompanied NO synthesis, rather than monitoring NO generation. Following the transformation of [^3H]arginine to [^3H]citrulline became a simple technique for monitoring NO synthase activity, and enzyme was first purified to homogeneity using this monitoring technique. Following homogenization of rat cerebellum, a two-column purification utilizing diethylaminoethyl (DEAE) cellulose followed by 2',5'-ADP agarose resulted in 6000-fold purification of NO synthase. The kinetic values determined for NO synthase included a K_m for L-arginine of $1.5\ \mu\text{M}$; a V_{\max} of $0.96\ \text{mmol min}^{-1}\ \text{mg}^{-1}$; and a K_i of $1.4\ \mu\text{M}$ for L-*N*^G-methylarginine. In addition, the purified brain enzyme required that calcium (Ca^{2+}) and calmodulin be added back in order to observe enzymatic activity. The purified brain NO synthase migrated as a single 150-kb band on SDS-PAGE. The purification of NO synthase from cultured macrophages was also achieved by utilizing 2',5'-ADP column chromatography and monitoring the purity of the eluate fractions by testing for the conversion of [^{14}C]arginine to [^{14}C]citrulline. Using ^{18}O -labeled dioxygen ($^{18}\text{O}_2$), it was determined by mass spectrometry that the ureido oxygen of L-citrulline derives from O_2 and not water as some researchers had earlier proposed. In contrast to the purified brain enzyme, calcium and calmodulin were not required for full activity of the purified macrophage NO synthase. From these publications a remarkable distinction could be seen in the regulation of NO synthesis, one purified enzyme that required Ca^{2+} /calmodulin for activity, and one that did not. Apart from distinctions based on tissue distribution, subcellular localization, and physiologi-

cal or pathophysiological roles of different NOS isoforms, the difference between calcium-activated and calcium-independent isoforms remains perhaps the most fundamental to enzymologists.

Following purification of macrophage inducible NO synthase (iNOS), enzyme activity required the addition of L-arginine, NADPH, and cytosolic cofactors including tetrahydrobiopterin. Researchers investigating other possible requirements for macrophage NO synthase discovered that flavin adenine dinucleotide (FAD) was needed for full enzyme activity. The addition of reconstituted cytosolic fractions to purified iNOS significantly enhanced the rate of NO synthesis. FAD alone increased activity more than twofold and suggested that NO synthase is a flavoprotein. NADPH was not required to regenerate tetrahydrobiopterin, and neither NADP^+ nor NADH or NAD^+ could substitute for NADPH. These findings suggested that NO synthesis by a macrophage NO synthase is an NADPH-utilizing FAD flavoprotein. Murine macrophage NO synthase ran as a single band with a relative molecular mass of 130 kDa. Gel filtration experiments estimated the native molecular mass to be 260 kDa, indicating that the native enzyme exists as a dimer. Also, fluorescence studies demonstrated the presence of one bound FAD and one bound flavin mononucleotide (FMN) per subunit.

The flavin requirement of NO synthase was confirmed when purified rat cerebellar NO synthase was cloned by screening a rat brain cDNA library. The resulting clones had an identical open reading frame of 4287 bases encoding a protein of 1429 amino acids and a relative molecular mass of 160 kDa, roughly corresponding to the size of the purified cerebellar enzyme. Sequence analysis revealed putative binding sites for calmodulin, NADPH, FAD, and FMN. Computerized sequence alignment with a FASTA program revealed remarkable similarity between cloned rat neuronal NO synthase (nNOS) and both cytochrome P-450 reductase and monooxygenase. The assay for detection of cytochrome P-450 monooxygenase (P-450) is spectroscopic, with an absorbance maximum near 450 nm for the carbon monoxide-reduced iron-heme component of the enzyme. Purified rat cerebellar NO synthase, like P-450, has a reduced CO absorbance maximum near 445 nm. A similar finding was also published for macrophage NO synthase, with a reduced CO absorbance maximum of 447 nm. Similar to the P-450BM3 isoform from bacteria, NO synthase is biochemically unique in that it contains both a reductase and a heme domain encoded in the same protein.

The characterization of the reductase and oxygenase domains of NO synthase was enabled first through their physical separation. This was accomplished by limited digestion with trypsin, which cuts the NO synthase monomer at one conserved site. Reconstitution of NO synthesis activity from isolated oxygenase and reductase domains of iNOS then provided important insights into the chemistry of catalysis. Although NO was not produced from L-arginine following reconstitution, it could be formed from the reaction intermediate N^G -hydroxy-L-arginine (L-NOHA). It was shown that the isolated iNOS reductase and oxygenase domains

each retained their separate catalytic functions but interacted to catalyze only the second step of NO synthesis. The tryptic fragments were still able to interact and transfer electrons, despite a requirement for exceptionally high 6:1 reductase:oxygenase stoichiometry for optimal catalysis. Electron transfer, being inefficient in the reconstituted enzyme, was likely limited to single electrons. However, the conversion of L-arginine to L-NOHA by NO synthase is hypothesized to be analogous to a mixed function oxygenase, in that it requires two electrons derived from NADPH. Such electron transfer was unlikely in the reconstituted enzyme, which explains why L-NOHA, but not L-arginine, could act as a substrate for NO generation.

The heme environment in cloned, expressed nNOS has been examined and the chemistry compared to the P-450 class of enzymes. The electron density marker line in the Raman spectrum of ligand-free Fe^{II} nNOS has a low frequency (1347 cm^{-1}), indicating a thiolate axial ligand on the heme. Also, the heme in resting nNOS is five-coordinate high spin and thereby differs from the resting state of most P-450s, which are predominantly six-coordinate low spin. Such differences in heme coordination make NO synthase a unique enzyme, which may explain its equally unique and elusive catalytic process.

The molecular cloning of macrophage NO synthase was accomplished by screening a cDNA library made from LPS-stimulated RAW 267.4 macrophages. The macrophage enzyme displays only 50% sequence identity to nNOS. Like nNOS, macrophage NO synthase has recognition sites for FAD, FMN, and NADPH and also has a consensus calmodulin-binding site. Macrophage NO synthase mRNA is very inducible; it was undetectable in quiescent macrophages but prominent 2–6 hr after LPS treatment.

NO synthase in vascular endothelium shares common biochemical and pharmacological properties with nNOS, including constitutive expression and Ca^{2+} /calmodulin-dependent activity. However, cloning and molecular characterization of NO synthase from bovine endothelial cells indicated specific differences. NO synthase was purified from bovine brain and tryptic peptides were sequenced. The sequence data was utilized to isolate clones encoding NO synthase from a bovine aortic endothelial cell cDNA library. A full-length NO synthase cDNA clone was isolated, representing a protein of 1205 amino acids with a molecular mass of 133 kDa. The deduced amino acid sequence of the endothelial NO synthase (eNOS) cDNA differs at numerous residues from the sequence determined for NO synthase purified from bovine brain (bovine nNOS). Endothelial NOS shares only 50–60% sequence identity to either the iNOS clone obtained from murine macrophages or the nNOS clone obtained from rat cerebellum. One of the striking differences between eNOS and other isoforms is myristoylation of the protein. This was demonstrated by the incorporation of [^3H]myristic acid into eNOS, and autoradiography of a partially purified protein run on SDS-PAGE.

NO synthase in the endothelium is a particulate enzyme, whereas other isoforms of NO synthase are soluble. The incorporation of myristate to eNOS makes the enzyme

particulate because fatty acid anchors the enzyme into the membrane. Through this lipid anchor, eNOS is associated with the Golgi in both cultured endothelial cells and intact blood vessels. Immunofluorescence studies using monoclonal antibodies have shown that eNOS is localized in a perinuclear region in both human and bovine endothelium, consistent with Golgi distribution. Colocalization with a Golgi-specific marker and immunoperoxidase studies demonstrated expression of eNOS on the cytoplasmic face. In relating this subcellular localization to functional significance it was noticed that a wild-type eNOS released several-fold more NO than cells expressing a mutant, nonacylated enzyme. Thus, acylation and association with the Golgi is important for eNOS function. In addition, palmitoylation of eNOS also regulates subcellular distribution and function, but in a manner that is more dynamic and responsive to extracellular signals.

NO synthase isolated from neurons (nNOS) or endothelium (eNOS) are both calmodulin dependent. Calmodulin binds reversibly to neuronal NO synthase in response to elevated Ca^{2+} and initiates the conversion of L-arginine to L-citrulline plus NO. Calmodulin binding allows NADPH-derived electrons to pass onto the catalytic heme. It has been demonstrated that calmodulin-triggered electron transfer to heme is independent of substrate binding and is required for NO synthesis. Inducible NO synthase isolated from cytokine-induced macrophages contains tightly bound calmodulin and catalyzes spontaneous electron transfer to the heme. This is consistent with the hypothesis that calmodulin binding regulates electron transfer in neuronal and endothelial isoforms and is a molecular switch that regulates catalytic activity on the basis of intracellular Ca^{2+} levels.

The primary sequence map of the three isoforms of human NO synthase is illustrated in Fig. 4. The structure of NO synthase has been investigated for both the murine in-

ducible and bovine endothelial isoforms. Crystal structures for dimerized oxygenase domains from murine iNOS (residues 1–498) with different cofactors and molecules bound at the active site have recently been obtained at a resolution near 2.6 Å. Tetrahydrobiopterin binding was essential for assembly, as it was determined to fold the central interface region, create a 30-Å-deep active-site channel, and tilt the heme for likely interactions with the reductase domain. Proximity of heme with H_2B and L-arginine suggests that tetrahydrobiopterin has electronic influences on heme-bound oxygen. L-Arginine binds to glutamic acid and stacks with heme in a hydrophobic pocket to prevent activated dioxygen from contacting water during the two distinct steps in NO synthesis.

Crystal structures of the oxygenase domain of bovine eNOS have also been recently obtained, and the description contrasts strikingly with that for murine iNOS. Crystals for eNOS in tetrahydrobiopterin-free and tetrahydrobiopterin-bound forms have been derived at resolutions of 1.95 and 1.9 Å, respectively. In both structures a zinc ion is tetrahedrally coordinated to pairs of symmetry-related cysteine residues at the dimer interface. This contrasts with iNOS, in which these conserved cysteines were reportedly involved in disulfide bonding between the dimers. The eNOS crystal structure suggests that the zinc-sulfur cluster plays a structural role in maintaining the integrity of the tetrahydrobiopterin-binding site. Such an intimate role for zinc in determining tetrahydrobiopterin binding disputes the reported structural importance of tetrahydrobiopterin in the murine iNOS model. Also, in the eNOS model, L-arginine was observed at the tetrahydrobiopterin site, suggesting a possible involvement of tetrahydrobiopterin in catalysis. The authors proposed a model in which a positively charged pterin radical participates in the catalytic cycle. The elucidation of NO synthase biochemistry and catalysis remains a center of sci-

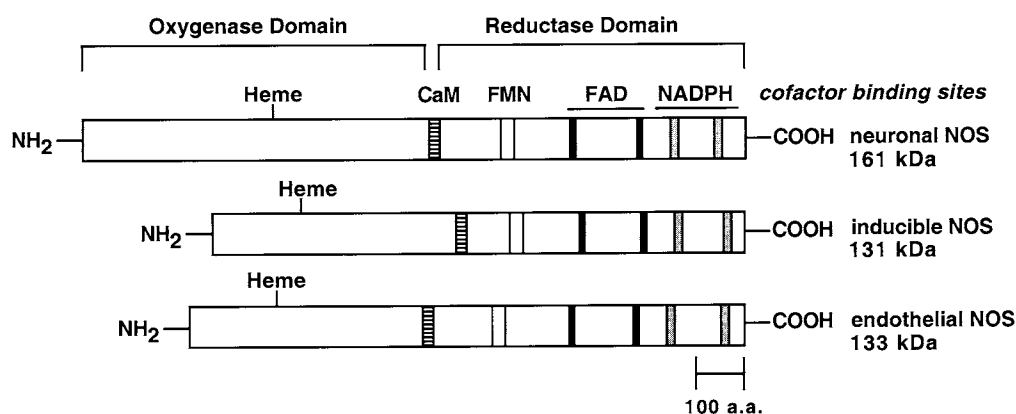

Figure 4 Primary sequence map of the three isoforms of human NO synthase and comparison to human NADPH-cytochrome P-450 reductase. All NO synthase isoforms are flavo-hemoproteins that utilize NADPH as a substrate for reducing equivalents. Illustrated in the diagram are binding sites for the cofactors including NADPH, FAD, FMN, and Ca^{2+} /calmodulin. Calmodulin is constitutively bound to the iNOS isoform and no Ca^{2+} is required for binding. The residues that bind tetrahydrobiopterin are not illustrated. The oxygenase domain of NO synthase contains a conserved cysteine residue that acts as an axial ligand for the heme iron.

entific debate. Future studies will undoubtedly clarify the roles of tetrahydrobiopterin and zinc in all three NO synthase isoforms.

Inactivation of NO

The inactivation of NO is unique with respect to other signaling molecules in that its inactivation is dependent solely on its nonenzymatic, chemical reactivity with other molecules. This section addresses the well-known oxidative mechanisms by which NO is inactivated. Reductive mechanisms, however, may also play a role in the inactivation of NO, but such reductive mechanisms are not well characterized.

NO readily reacts with oxyhemoglobin or oxymyoglobin to give nitrate (NO_3^-) and the oxidized hemoproteins, met-hemoglobin and metmyoglobin [Eq. (1)].

This reaction may be the primary mechanism by which the movement and concentration of NO are controlled *in vivo*. Due to the high concentrations of oxyhemoglobin in the body, its reaction with NO may be the primary metabolic as well as the primary detoxification mechanism for NO. Indeed, the measurement of NO_3^- in blood or urine is often used as an indirect indicator of *in vivo* NO production. In addition to the interaction of NO with oxyhemoglobin or oxymyoglobin, NO can react with the met and deoxy forms of hemoglobin or myoglobin [Eqs. (2) and (3)].

NO is capable of reducing Fe(III) to Fe(II) resulting in the formation of nitrite (NO_2^-) and deoxyhemoglobin or deoxymyoglobin. The reaction of Fe(II) heme in deoxyhemoglobin or deoxymyoglobin with NO leads to an essentially irreversible Fe(II)–NO complex. The physiological relevance of these reactions, however, is unclear.

NO interacts with superoxide radical, the one-electron reduction product of O_2 in a near diffusion controlled reaction to form peroxynitrite ($^-\text{OONO}$) [Eq. (4)].

Peroxyntirite has only a fraction of the biological activity of NO and, therefore, this reaction represents an inactivation mechanism for NO. Peroxyntirite, however, is extremely electrophilic and can, therefore, behave as a potent oxidant. Under pathophysiological conditions involving mitochondrial dysfunction, where high concentrations of superoxide may be formed, the reaction of NO with superoxide to form peroxynitrite may lead to the oxidation of a variety of biological molecules and modification of cellular function. Under these conditions peroxynitrite formation should not be seen as a mechanism of inactivation of NO. In most cases,

the physiological concentrations of superoxide are very low due to the high levels of superoxide dismutase in cells. Under physiological conditions, therefore, the reaction of NO with superoxide leads to peroxynitrite levels that probably have little or no effect on cellular function. Under these conditions, peroxynitrite formation can be considered as a mechanism of inactivation of NO.

Although the Lewis dot formalism does not indicate it, molecular oxygen (O_2) contains two unpaired electrons and is therefore a diradical. NO, itself being a radical, reacts with O_2 to produce NO_2 [Eq. (5)]. NO_2 can then dimerize to form N_2O_4 or react with another NO molecule to form N_2O_3 [Eqs. (6) and (8)]. Both N_2O_4 and N_2O_3 are hydrolytically unstable and will react with water to give $\text{NO}_2^- + \text{NO}_3^-$ in the case of N_2O_4 or 2NO_2^- in the case of N_2O_3 [Eqs. (7) and (9)].

In aerobic aqueous solutions NO_2^- is the predominant reaction product of the reaction between O_2 and NO. Therefore, it is reasonable to assume that the mechanism involving N_2O_3 formation is predominant in the inactivation of NO by O_2 . It was previously thought that this chemistry involving NO and O_2 was irrelevant *in vivo* because the reaction is second order with respect to NO and therefore NO would not reach high enough concentrations in the cell for this reaction to be physiologically important. However, recent studies have shown that because of the lipid solubility of NO, it preferentially partitions into lipid membranes leading to locally high concentrations of NO that likely make this chemistry physiologically relevant.

Endogenous S-Nitrosothiols

Thiols are by far the most abundant electrophile present *in vivo*, reaching concentrations greater than 1 mM. NO and related species have been shown to react readily with both protein and low-molecular-weight thiols to form S-nitrosothiols. An increasing number of proteins such as albumin, p21^{ras}, glyceraldehyde 3-phosphate dehydrogenase, and hemoglobin as well as the low molecular weight thiols, cysteine and glutathione, have been found to be S-nitrosylated *in vivo*. In addition, many proteins have been shown to be S-nitrosylated in cultured cells and in purified enzyme systems. It is becoming evident, with the discovery of new S-nitrosylated molecules, that the formation of S-nitrosothiols may be important in a variety of biologically diverse processes.

Although sufficient evidence exists that EDRF is NO, the argument has been advanced that EDRF might be a more chemically stable adduct of NO, such as an S-nitrosothiol.

NO appears to circulate in blood primarily as the *S*-nitroso adduct of serum albumin and may act as a reservoir for storing NO. Serum albumin contains a single free sulfhydryl group and is the most abundant source of reduced thiol in the plasma because the plasma concentration of serum albumin is approximately 0.5 mM. Moreover, the free sulfhydryl group in serum albumin is particularly susceptible to *S*-nitrosylation. *S*-Nitroso-albumin is relatively stable when compared to NO, having a half-life in phosphate buffer, pH 7.6, of approximately 24 hr. The concentration of free NO in plasma is approximately 4 nM, whereas the concentration of *S*-nitroso-albumin is 5 μ M (about 80% of the total plasma nitrosothiols), a difference of four orders of magnitude. In animals, administration of exogenous *S*-nitroso-albumin leads to vasorelaxation, decreased mean arterial blood pressure, and inhibition of platelet aggregation, whereas administration of NO synthase inhibitors leads to decreased concentrations of plasma nitrosothiols, vasoconstriction, and increased mean arterial blood pressure. This suggests not only that *S*-nitroso-albumin possesses the properties of NO but also that the formation of *S*-nitrosothiols in the plasma is dependent on NO synthase activity.

The hypothesis has been forwarded that *S*-nitroso-albumin may act as a reservoir for storing or carrying NO. The question arises as to how NO is transferred from *S*-nitroso-albumin to intracellular targets if any appreciable transfer does occur. Large proteins, such as albumin, can not cross the plasma membrane and any free NO released would be scavenged by the iron in hemoglobin. Low-molecular-weight thiols such as cysteine or glutathione may act to transfer NO from *S*-nitroso proteins across the plasma membrane to intracellular targets. *S*-Nitrosocysteine (CysNO) and *S*-nitrosogluthione (GSNO) have been detected in plasma at concentrations of 0.3 and 0.1 μ M, respectively. L-Cysteine enhances the vasodilatory and platelet inhibitory effects of *S*-nitroso-albumin, and when rabbits are infused with *S*-nitroso-albumin, CysNO levels have been shown to increase by as much as 12-fold.

Another protein that has been proposed to act as a carrier of NO in the blood is hemoglobin. *S*-Nitroso-hemoglobin concentrations have been reported to be 0.3 μ M in arterial blood and 0.03 μ M in venous blood. Oxygenation of hemoglobin promotes the binding of NO to cysteine- β 93, forming *S*-nitroso-hemoglobin. Deoxygenation of *S*-nitroso-hemoglobin causes an allosteric change in the protein that promotes NO release. Accordingly, the proposal has been advanced that hemoglobin can sense the physiological oxygen gradient and bring local blood flow in line with oxygen requirements by releasing NO in poorly oxygenated regions, thereby causing vasorelaxation and increased blood flow.

Cell surface protein disulfide isomerase (PDI) has been implicated in the transfer of NO across the plasma membrane. PDI plays an important role in maintaining the redox status of plasma membrane protein thiols, catalyzing protein disulfide bond formation, reduction, and isomerization. PDI is proposed to be both directly and indirectly involved in the cellular entry of NO. PDI may act directly by

catalyzing transnitrosation reactions and indirectly by maintaining thiols in their reduced state, which is required for their reaction with NO.

GSNO may act as an intracellular carrier of NO. Glutathione is a tripeptide containing a single sulfhydryl group and is present intracellularly at concentrations greater than 1 mM. GSNO may be involved in the transfer of NO from NO synthase to guanylate cyclase. In isolated rat hearts a Cu⁺-specific chelator prevented bradykinin-induced cGMP accumulation but did not affect cGMP accumulation due to exogenous NO sources. In addition, activation of NO synthase in the presence of glutathione led to the formation of GSNO. Since Cu⁺ is known to catalyze the release of NO from *S*-nitrosothiols, it was concluded that GSNO must be involved in the pathway. In addition to its possible involvement in the NO–cGMP signaling pathway, GSNO has been proposed to act as an intracellular store of NO in brain tissue. GSNO has been detected by HPLC coupled to mass spectrometry in rat brain tissue.

Many cysteine-containing proteins, including enzymes, ion channels, and transcription factors, have been shown to be *S*-nitrosylated and their function modified. Although there is limited evidence of intracellular *S*-nitrosylated proteins *in vivo*, the capacity of NO to interact with thiols to form *S*-nitrosothiols lends itself to the possibility that *S*-nitrosylation could be a global mechanism by which NO regulates protein function. In addition, many proteins have been shown to be *S*-nitrosylated and their function modified *in vitro*, supporting the idea of a global regulatory role. One of the earliest examples of a protein whose function is modified by *S*-nitrosylation is glyceraldehyde 3-phosphate dehydrogenase (GAPDH). GAPDH is a ubiquitous protein involved in the glycolytic pathway. It contains 16 cysteine residues, four of which are known to be essential for enzymatic activity. Using conditions that produced chronic inflammation in liver it was shown that increases in NOS activity correlated with decreased GAPDH activity. Exposure of purified GAPDH to authentic NO led to the modification of four cysteine residues per molecule. The modification of GAPDH by NO was reversible by addition of the thiol reducing agent, dithiothreitol (DTT), which is consistent with the mechanism of *S*-nitrosylation. Modification of the cysteine residues by exposure to NO led to decreased enzyme activity, which was also shown to be reversible. Subsequently, *S*-nitrosylation of GAPDH was shown to facilitate NADH attachment and, consequently, irreversible inhibition of GAPDH activity.

NO is capable of inhibiting seven members of the caspase family via *S*-nitrosylation. The caspases are a group of cysteine proteases that are involved in apoptotic signal transduction and cytokine maturation and contain an active site cysteine required for enzymatic activity. Of the seven caspases inhibited by *S*-nitrosylation, caspase-3 has gained the most attention because it is involved in the apoptotic signaling pathway. Both endogenous and exogenous NO were capable of inhibiting apoptosis in hepatocytes, and this correlated with a decrease in caspase-3 activity. As with

GAPDH, purified caspase-3, along with six other members of the caspase family, was inhibited by NO and inhibition was reversed by DTT, suggesting that S-nitrosylation is involved.

NO has been shown to directly activate both the calcium-dependent potassium (K^+_{Ca}) channel in vascular smooth muscle and the cardiac calcium release channel (CRC). The K^+_{Ca} channel is activated by NO concentrations in the order of 0.2 μM . Activation of the K^+_{Ca} channel by NO was blocked by pretreatment with the sulfhydryl-modifying agent *N*-ethylmaleimide. In addition, *N*-ethylmaleimide did not prevent the activation of the K^+_{Ca} channel by other substrates, indicating that *N*-ethylmaleimide did not inactivate the channel itself but rather prevented the activation by NO. This suggests direct modification of cysteine residues in the K^+_{Ca} channels by NO, but S-nitrosylation was not shown to be the definitive mechanism. CRC, when isolated from canine hearts, was shown to contain S-nitrosothiol groups, which were eliminated by addition of DTT. CRC contains approximately 84 free thiols and is activated by S-nitrosylation of as few as 12 thiol residues, the activation being reversible by DTT. In contrast, oxidation of up to 24 thiol residues per CRC did not lead to activation of CRC. These observations indicate not only that S-nitrosylation can activate CRC, but that CRC can distinguish nitrosative from oxidative signals.

Another molecule of interest that has been shown to be S-nitrosylated is p21^{ras}. NO promotes guanine nucleotide exchange on p21^{ras} by nitrosating a specific cysteine residue in a highly conserved region of the GTP binding site. This leads to downstream signaling via multiple MAP kinase subgroups and translocation of the transcription factor NF κ B. Substitution of the cysteine residue with a serine residue prevented S-nitrosylation of p21^{ras} and NO no longer stimulated guanine nucleotide exchange. These findings suggest a role for multiple MAP kinase signaling pathways in the cellular response to NO via a cGMP-independent mechanism.

NO–cGMP Signal Transduction Pathway

The NO–cGMP signal transduction pathway is employed by NO to carry out many of its biological effects. Adding to the intricacy and complexity of this system is the cross talk that occurs between this signal transduction pathway and the other major pathways in the cell including those involving cAMP and phosphoinositides. cGMP was discovered almost four decades ago in rat urine. This was the result of a systemic search for an analog of its better known cousin, cAMP. However, cGMP remained obscure relative to cAMP for many years for a number of reasons. No clear function could be assigned to cGMP in part because of a lack of a selective agonist of soluble guanylate cyclase. However, this changed in the 1970s with the discovery that the so-called nitrovasodilators cause smooth muscle relaxation by activating guanylate cyclase. Then in the mid 1980s came the report that the mediator of the severe secretory diarrhea seen in gastroenteritis caused by heat stable enterotoxin releasing *Escherichia*

coli was cGMP. The discoveries of natriuretic peptides, guanylin, and NO as endogenous activators of guanylate cyclase led to the appreciation of cGMP as a second messenger of immense biological significance and potential. cGMP represents a second messenger that acts on three main classes of effector proteins: cGMP-dependent protein kinases (cGK), cGMP-gated ion channels (CNG), and cGMP-regulated phosphodiesterases (PDE). These effector proteins mediate protein phosphorylation, cation influx, and cyclic nucleotide metabolism, respectively. The biological actions of cGMP are terminated by its breakdown by phosphodiesterases.

cGMP, through its effector proteins, mediates several of the physiological functions of NO including regulation of smooth muscle tone, inhibition of platelet aggregation, regulation of neurotransmission, and chloride and water secretion in the intestines. However, as indicated previously and in other chapters in this book, several of the effects of NO are mediated by cGMP- (and guanylate cyclase-) independent mechanisms. These, among other things, include reactions of NO with metal and thiol centers of target molecules. Figure 5 illustrates the signal transduction pathway for the NO–cGMP system and indicates some NO-elicited effects that are not mediated by cGMP. cGMP-dependent protein kinases have emerged as signal transduction mediators of great importance. cGMP was identified in rat urine in 1963, but it was not until 1970 that cGK, the first target of cGMP to be identified, was discovered in lobster tail muscle. Subsequently, PDE and CNG were recognized as additional targets of cGMP. cGK belongs to the large superfamily of protein kinases. These enzymes regulate the activity of their target proteins by catalyzing the transfer of a γ -phosphoryl group of ATP to a hydroxyl group on serine, threonine, or tyrosyl residues present in the target proteins. Within the protein kinase superfamily, cGKs are related to cAMP-dependent protein kinases (cAK). 8-Bromo-cGMP and 8-pCPT-cGMP are potent cGK activators that have been widely used to study the role of cGK in intact cells. These compounds are ideal for this purpose as they permeate cellular membranes to some extent, are relatively resistant to PDE, and are fairly selective for cGK. cGK antagonists such as Rp-8-Bromo-cGMPS and Rp-8-pCPT-cGMPS are important additional chemical probes used to investigate the physiological functions of cGKs.

Two isoforms of cGKs have been identified and cloned in mammalian cells. They exhibit greater than 50% sequence homology and have similar structural organization. However, they differ in their cellular and subcellular distribution and consequently in their assigned biological roles. cGK Type I is predominantly a cytosolic protein, whereas cGK Type II is tightly bound to membranes. Type I is more widely expressed with high levels of the enzyme being found in vascular smooth muscle cells, platelets, aortic and pulmonary endothelial cells, and cerebellum. Type II has a more limited distribution with high levels being expressed in intestinal epithelial cells and also in brain and kidney. These localizations suggest that Type I is more important in the cardiovascular system, whereas Type II plays a more

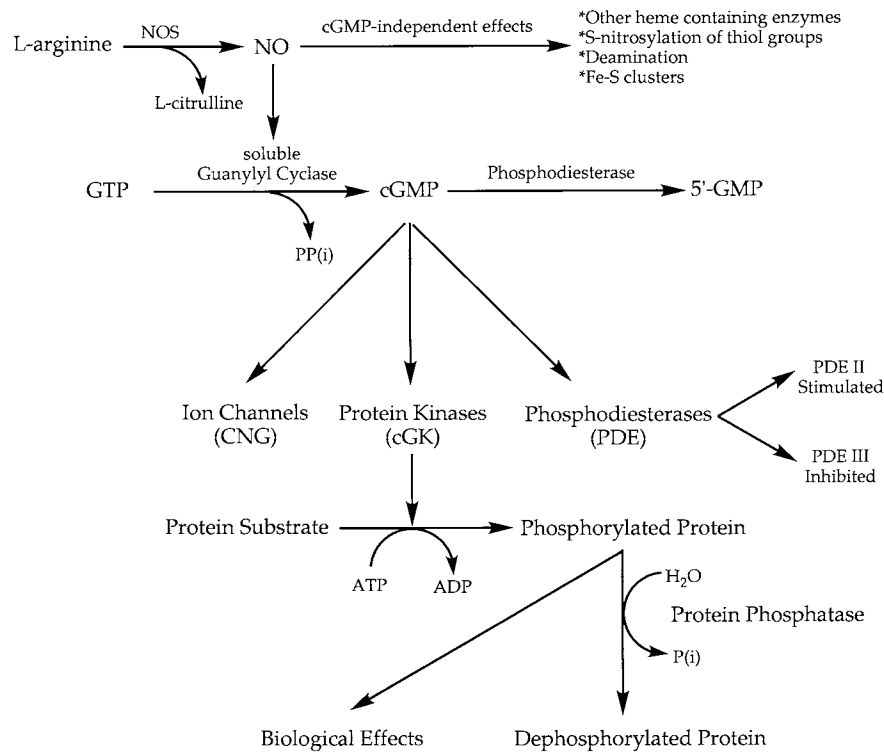

Figure 5 Signal transduction pathway for the NO–cGMP system in mammalian cells. NO generated from L-arginine by NO synthase (NOS) isoforms activates soluble guanylyl (guanylate) cyclase, thereby increasing production of cGMP. The cGMP can be degraded by phosphodiesterase or can bind to other proteins including ion channels, protein kinases, and phosphodiesterases as illustrated. cGMP can either activate or inhibit specific phosphodiesterase isoforms. Binding of cGMP to protein kinases causes their activation and subsequent phosphorylation of proteins. The phosphorylated proteins can cause or lead to a biological effect and are generally inactivated by dephosphorylation caused by protein phosphatases. Although many of the biological actions of NO are mediated by cGMP via this signal transduction pathway, some effects of NO are cGMP independent, such as those illustrated in the upper right corner of the figure.

important role in ion transport in the intestine and perhaps the kidney.

Smooth muscle relaxation is a key physiological function of NO that is mediated by cGMP. Smooth muscle contraction has been shown to be dependent on phosphorylation of the regulatory light chain of myosin by myosin light chain kinase (MLCK). Activation of MLCK is in turn dependent on a rise in free intracellular Ca^{2+} levels. cGK is thought to lower free intracellular calcium levels by multiple mechanisms including inhibition of the phospholipase C (PL-C)/inositol trisphosphate (IP_3) pathway and direct action on various ion channels in the membrane. cGK might also activate a phosphatase that causes dephosphorylation of MLCK. The antiplatelet action of NO represents another major physiological function of NO that is GMP dependent. The inhibition of platelet activation, adhesion, secretion, and aggregation has been shown to be mediated primarily by cGK. A major mechanism by which cGK brings this about is by decreasing intracellular free calcium by some of the mechanisms indicated previously but especially by inhibition of the PL-C/ IP_3 pathway.

An important and interesting target of cGK I is a cytoskeletal protein called VASP (vasodilator-associated phospho-

protein). This protein interacts with other cytoskeletal proteins and might be involved in the coordination of different signal transduction pathways. Evidence suggests that VASP, in addition to other things, is important in the enhancement of actin filament formation and inhibition of integrin function. Phosphorylation of VASP might be one of the mechanisms by which cGMP–cGK regulates cell adhesion and migration. Another mechanism might be through regulation (inhibition) of the MLC/MLCK system. MLC phosphorylation leads to assembly of myosin into bipolar filaments that enhance actin tension. This rise in actin tension has multiple effects including clustering of integrin receptors, activation of focal adhesion kinases, and recruitment of various signaling proteins into focal adhesions. By preventing this phosphorylation of MLC or promoting the dephosphorylation of phosphorylated MLC, cGMP–cGK might inhibit cellular adhesion, aggregation, and migration. In addition to being of importance in platelet adhesion and aggregation, the cGMP–cGK pathway may be significant in the regulation of many physiological and pathophysiological processes including embryogenesis, wound healing, tumor invasion and metastasis, and atherosclerosis.

In the intestines, cGMP is involved in the secretion of chloride and water. CFTR, a Cl^- channel encoded by the CF (cystic fibrosis) gene, is thought to play a pivotal role in the secretory response to cGMP. Several mechanisms have been proposed to explain how cGMP might modulate CFTR function. Recent reports suggest that cGK II plays a key role in this transduction pathway.

The other major effector proteins that cGMP acts on are ion channels. These ion channels belong to the cyclic nucleotide gated (CNG) ion channel family. CNG channels are heteromeric proteins that are directly and cooperatively opened by the binding of cyclic nucleotides at a site in their C terminus. Once opened, the channels allow the influx of Na^+ and Ca^{2+} into the cell. This triggers a variety of biochemical cascades with diverse biological effects. Functionally, CNG channels belong to the class of ligand-gated ion channels where the binding of a ligand (cAMP or cGMP) activates them. However, on the basis of their primary sequence, CNG channels structurally belong to the superfamily of voltage-gated ion channels. The CNG channels are a relatively recent discovery. Before this time, cyclic nucleotides were thought to affect ion channel function only through cyclic nucleotide-dependent protein kinases and channel phosphorylation. Direct binding of the cyclic nucleotides is a much faster method of modulating ion channel activity. The first member of the CNG family to be identified was the cGMP-activated cation channel of rod and cone photoreceptors in the retina. A CNG channel with more or less equal sensitivity to both cAMP and cGMP was detected in the membranes of olfactory neurons. Earlier it was thought that the CNG might be limited to the visual and olfactory sensory system but now it is known that CNG channels are much more widespread. More recent findings are the discovery of a related channel in cardiac tissue that appears to generate pacemaker current and the discovery of a similar channel in sea urchin sperm.

Active cross talk occurs between the NO–cGMP signal transduction pathway and other major signal transduction pathways and second messengers. This lends more complexity and diversity to the pathway. One important interaction is between cGMP and cAMP. One of the ways in which cGMP modulates cAMP is by regulating key enzymes called phosphodiesterases (PDE). PDE represent the third major target effector protein for cGMP. They break down the cyclic nucleotides, cAMP and cGMP, thereby terminating their actions in the process. Nine different types of PDEs have been identified to date. They differ in their substrate specificity, sensitivity, distribution, and regulation. Two of these nine PDEs are regulated by cGMP. PDE III is inhibited by cGMP, resulting in higher levels of cAMP. PDE II is stimulated by cGMP, causing the levels of cAMP to go down. Examples of this type of interaction are evident in platelets and smooth muscle cells where cGMP potentiates the effects of cAMP by inhibiting PDE III. Another mechanism by which cGMP can use the cAMP pathway is by cross-activating cAMP-dependent kinases (cAK). This occurs at higher levels of cGMP ($>5 \mu\text{M}$). An example of this is seen in colonic T84

cells. This method of cross-activation has so far been less well-documented in the cardiovascular system. However, the antiproliferative effects of cGMP are thought to be at least partly dependent on cross-activation of cAK. Opposite cross-activation, that is, activation of cGK by cAMP, also occurs and is thought to be partly responsible for the vaso-relaxant effects of cAMP. It has also been shown that activated guanylate cyclase can synthesize cAMP.

Potent and selective inhibitors and activators for many of the multiple steps in the NO–cGMP signal transduction pathway are still not available. Hence caution needs to be exercised in assigning biological roles to this pathway. Discovery of new pharmacological tools to manipulate this fascinating signal transduction pathway in a selective manner is of great pharmacological and therapeutic interest, as exemplified by the discovery of the selective PDE V inhibitor sildenafil (Viagra).

The Chemical Properties of Nitric Oxide and Related Nitrogen Oxides

Jon M. Fukuto, Jennifer Y. Cho, and Chris H. Switzer

*Department of Pharmacology, UCLA School of Medicine, Center for the Health Sciences
Los Angeles, California*

DUE TO THE DISCOVERY OF ITS ENDOGENOUS BIOSYNTHESIS AND DIVERSITY OF ITS BIOLOGICAL ACTIONS, NITRIC OXIDE (NO) IS A MOLECULE OF EXTREME PHYSIOLOGICAL, PHARMACOLOGICAL, AND PATHOPHYSIOLOGICAL INTEREST. MUCH OF THE BIOLOGICAL UTILITY OF NO IS DUE TO ITS UNIQUE CHEMICAL INTERACTIONS WITH BIOLOGICAL MOLECULES. THUS, AN UNDERSTANDING OF THE BASIC CHEMICAL PROPERTIES OF NO, AND DERIVED SPECIES, WILL PROVIDE INSIGHT INTO THE INTIMATE MECHANISMS OF ITS BIOLOGICAL ACTIVITY. AS A PREFACE TO UNDERSTANDING THE PHYSIOLOGICAL AND PATHOPHYSIOLOGICAL PROPERTIES OF NO, A DISCUSSION OF SOME OF THE BIOLOGICALLY RELEVANT CHEMISTRY OF NO IS PROVIDED.

Nitric oxide ($\cdot\text{NO}$) is a simple, diatomic molecule possessing unique and fascinating chemistry.¹ Indeed, the utility of $\cdot\text{NO}$ as a biological effector and/or mediator is due to some of its novel chemical properties along with the properties of other nitrogen oxides derived from it. Because the biological and physiological roles of $\cdot\text{NO}$ and related species will be addressed in detail in subsequent chapters, presented herein is a discussion of the physiologically relevant chemical properties of $\cdot\text{NO}$ and other nitrogen oxides and how these properties may be utilized to confer specificity to its biological actions. For more comprehensive treatments of general $\cdot\text{NO}$ and nitrogen oxide chemistry, other reviews are available (Gilbert and Thomas, 1972; Schwartz and White, 1983; Vos-

per, 1975; Bonner and Hughes, 1988; Ragsdale, 1973; Bonner and Stedman, 1996).

$\cdot\text{NO}$ and the $\cdot\text{NO}$ Dimer (NO_2)

Nitric oxide is a colorless gas at room temperature and pressure (boiling point -151.7°C). The maximum solubility of $\cdot\text{NO}$ (at 1 atm partial pressure) in water at room temperature and pressure is approximately 2 mM which is slightly higher than the solubility of dioxygen (O_2) in water. Also, like O_2 , $\cdot\text{NO}$ is somewhat lipophilic and possesses 6- to 8-fold higher solubility in nonpolar solvents (Shaw and Vosper, 1977) and lipid membranes compared to water. Thus, the rates of $\cdot\text{NO}$ reactions in a hydrophobic environment can be dramatically increased (with O_2 , e.g.) over that found in water due to its increased concentration (Liu *et al.*, 1998).

It becomes immediately evident from a Lewis dot depiction that $\cdot\text{NO}$ has one unpaired electron and thus is formally a free radical species (Fig. 1). The radical nature of $\cdot\text{NO}$ is evidenced by its ability to react with other species with

¹ The nomenclature used herein for the nitrogen oxides is somewhat antiquated and can lead to confusion when attempting to assign oxidation states based on suffixes. However, due to the prevalence of these terms in the current biochemical and physiological literature, we will continue to use the outdated terms in this chapter (e.g., nitric oxide instead of nitrogen monoxide, nitrous oxide instead of dinitrogen monoxide). For a treatise on the correct nomenclature for the nitrogen oxides, the reader is referred to the article by Koppenol and Traynham (1996).

Figure 1 Lewis dot structure of $\cdot\text{NO}$.

unpaired electrons such as O_2 , superoxide (O_2^-) and other radical species (the details of these processes will be discussed later). However, at room temperature and pressure, $\cdot\text{NO}$ has little propensity to react with itself in a radical-radical dimerization process. At first glance, this may seem curious since dimerization would lead to a structure ($\text{ON}-\text{NO}$) whereby all atoms have a full complement of eight valence electrons and, therefore, would satisfy the octet rule. In order to reconcile this apparent anomaly, the molecular orbitals of $\cdot\text{NO}$ must be considered.

Simple combination of the nitrogen and oxygen atomic orbitals gives the following set of molecular orbitals (Fig. 2). In order of increasing energy, the molecular orbitals consist of a σ bonding orbital (σ^b) and a corresponding σ antibonding orbital (σ^*), two degenerate π bonding orbitals (π^b_{xy}), one σ bonding orbital (σ^b_z , only slightly higher in energy than the π bonding orbitals), two degenerate antibonding π orbitals (π^*_{xy}), and a high energy σ antibonding orbital (σ^*_z) (Jorgensen and Salem, 1973). Since the total number of valence electrons in the $\cdot\text{NO}$ molecule is 11 (five from nitrogen and six from oxygen), the low-lying σ bonding and σ antibonding orbitals along with the bonding π and σ orbitals are all filled. However, the last electron must reside in a π^* antibonding orbital. In molecular orbital terminology, the electronic structure of $\cdot\text{NO}$ is $\text{KK}(\sigma^b)^2(\sigma^*)^2(\pi^b_{xy})^4(\sigma^b_z)^2(\pi^*_{xy})^1$. Thus, $\cdot\text{NO}$ has a net bond order of 2.5 because there is one electron in the π^* antibonding orbital. When $\cdot\text{NO}$ forms a dimer ($\text{O}=\text{N}-\text{N}=\text{O}$), the overall bond order for the molecule is 5. Therefore, since there is no net gain in overall bonding when $\cdot\text{NO}$ dimerizes and entropy would favor the monomer, $\cdot\text{NO}$ exists as a monomer at room temperature and pressure.

The above rationale for the observation that $\cdot\text{NO}$ exists primarily as a monomeric species at room temperature and pressure is purely qualitative. This issue has also been examined quantitatively. The experimental dimerization energy for two $\cdot\text{NO}$ molecules has been measured to be in the range of only 2–4 kcal/mol (Hetzler *et al.*, 1991; Dkhissi *et al.*, 1997; Forte and van den Bergh, 1978). In order to understand the low magnitude of this bond energy, one needs to examine the $\cdot\text{NO}$ dimer itself. The $\cdot\text{NO}$ dimer has been the subject of considerable experimental and theoretical study (East, 1998; East *et al.*, 1998; Casassa *et al.*, 1986; Williams and Murrell, 1971; Kukolich, 1982; Lee *et al.*, 1990; Tonner *et al.*, 1983; Jursic, 1995; Casassa *et al.*, 1988). The N–N bond in the dimer is not only unusually weak but is also extremely long (2.263 Å) (McKellar *et al.*, 1995). For comparison, the covalent bond in hydrazine, H_2NNH_2 , has an N–N bond dissociation energy of 65.8 kcal/mol and an N–N bond length of 1.45 Å (McMillen and Golden, 1982). The N–N interaction in the $\cdot\text{NO}$ dimer is considerably weaker than a covalent bond and yet cannot be explained entirely by van der Waals interactions, which provide stabilization on the order of only tenths of a kilocalorie per mole. Interestingly, $\cdot\text{NO}$ dimer formation does very little to disturb the nitrogen–oxygen orbital overlap. The experimental N–O bond distance in the dimer is 1.1515 Å (McKellar *et al.*, 1995) whereas the N–O bond distance in the monomer is 1.151 Å (Huber and Herzberg, 1979). The predicted ground state for the $\cdot\text{NO}$ dimer is singlet and a symmetric planar *cis* conformation is favored (Ha, 1981; Skaarup *et al.*, 1976). This more sterically hindered *cis* geometry is lower in energy than the *trans* configuration, because there is favorable orbital overlap between the oxygens giving a weak O–O bond (Fig. 3). This indicates that the electrons in the N–N σ bond of the dimer are delocalized over the entire dimer structure which would predict a weak N–N bond.

A partial rationale for the unusually long and weak N–N bond in the $\cdot\text{NO}$ dimer may also be found in an examination of the nature of the unpaired electron in the $\cdot\text{NO}$ monomer.

Figure 2 Molecular orbital diagram for $\cdot\text{NO}$.

Figure 3 Structure of the $\cdot\text{NO}$ dimer.

Theoretical studies confirm that the unpaired radical electron of nitric oxide resides in a π^* orbital (Perez Jigato *et al.*, 1995; East, 1998; Duarte *et al.*, 1998) (also see Fig. 2). The radical does not reside completely on the nitrogen but is shared between the nitrogen and the oxygen (which may explain the existence of a weak O–O bond in the *cis* conformation of the dimer). However, the nitrogen does have a higher orbital coefficient, which explains the observed radical chemistry predominating at the nitrogen (i.e., reaction of $\cdot\text{NO}$ with other radicals occurs through the nitrogen atom). Thus, the weak N–N bond in the $\cdot\text{NO}$ dimer can be attributed to a variety of effects including the weak attractive forces of the delocalized electrons in the π^* molecular orbitals as well as electronic repulsion of the lone pair electrons on the adjacent, bonding nitrogens.

$\cdot\text{NO}$ and Its Relationship to Other Nitrogen Oxide Species

Within the series of redox related nitrogen oxides, $\cdot\text{NO}$ occupies a central position (Fig. 4). Thus, $\cdot\text{NO}$ can conceivably be either oxidized or reduced to generate a variety of species and, indeed, it is likely that both oxidative and reductive pathways for $\cdot\text{NO}$ exist in a physiological environment.

The Reaction of $\cdot\text{NO}$ with O_2 and O_2 -derived Species in Aqueous Solution

Based on the argument above, $\cdot\text{NO}$ is considered a free radical in spite of the fact that it does not have the tendency to dimerize at room temperature and pressure. Nitric oxide will, however, react with other species with unpaired electrons. One of the most biologically relevant reactions of this type is the reaction of $\cdot\text{NO}$ with O_2 . As a ground state triplet, O_2 has two unpaired electrons [the electron configuration for

O_2 is $\text{KK}(\sigma_g^2)(\sigma_g^*)^2(\pi_g^b)^4(\sigma_g^b)^2(\pi_g^*)^2$] and therefore possesses some chemical characteristics of a biradical. As such, O_2 is known to react with other radical species. Since O_2 has two unpaired electrons, the product of O_2 and $\cdot\text{NO}$ (and other radicals) still has one unpaired electron which can react further. Thus, the reaction of $\cdot\text{NO}$ with O_2 consumes two equivalents of $\cdot\text{NO}$ to give two equivalents of nitrogen dioxide ($\cdot\text{NO}_2$) possibly via the reactions (1), (2), and (3).

Although the reaction of 2 $\cdot\text{NO}$ molecules with O_2 to generate 2 $\cdot\text{NO}_2$ molecules may occur via the three-step sequence indicated by reactions (1)–(3), it has also been postulated that this process can proceed via reaction of O_2 with an $\cdot\text{NO}$ dimer (NO_2 species (e.g., see Olbregts, 1985). That is, the initial step may involve the generation of an $\cdot\text{NO}$ dimer which, in turn, reacts with O_2 to give two $\cdot\text{NO}_2$ molecules. Regardless of which mechanism is in operation, the observed kinetic order of the $\cdot\text{NO}_2$ forming reaction would be second order in $\cdot\text{NO}$ and first order in O_2 .

Nitrogen Dioxide

Like $\cdot\text{NO}$, $\cdot\text{NO}_2$ also possesses an unpaired electron which can be delocalized throughout the molecule (Fig. 5). As the structures in Fig. 5 demonstrate, assigning a full complement of eight electrons around two of the three atoms in NO_2 leaves the unpaired electron on the remaining atom.

Unlike $\cdot\text{NO}$, $\cdot\text{NO}_2$ is a fairly potent oxidant as indicated by a reduction potential of 1.04 V for the $\cdot\text{NO}_2/\text{NO}_2^-$ couple (Stanbury, 1989). Thus, the reaction between two relatively innocuous oxidizing agents, O_2 and $\cdot\text{NO}$, generates a more potent oxidant, $\cdot\text{NO}_2$. There are a variety of potential reaction pathways by which $\cdot\text{NO}_2$ can cause oxidation: hydrogen atom abstraction, addition to unsaturated bonds, and electron transfer reactions (for an excellent review of $\cdot\text{NO}_2$ oxidation chemistry, see Huie, 1994). Generally speaking, H-atom abstraction by $\cdot\text{NO}_2$ in solution is extremely slow and probably only relevant to biological systems with activated hydrogen atoms (i.e., weak atom–hydrogen bond). The reversible addition of $\cdot\text{NO}_2$ to olefins generates initially a nitroalkyl radical species which can react with another radical species such

Figure 4 Redox relationship of $\cdot\text{NO}$ to other nitrogen oxide species. The Roman numerals in the chemical formulas refer to the oxidation state of the nitrogen atom. Note: for the sake of simplicity, two prevalent nitrogen oxides that are oxidized relative to $\cdot\text{NO}$, peroxynitrite ($\cdot\text{OONO}$) and nitrogen dioxide ($\cdot\text{NO}_2$), are not shown in this scheme (and will be discussed later).

Figure 5 Lewis dot depiction and resonance forms of $\cdot\text{NO}_2$.

as a second molecule of $\cdot\text{NO}_2$ or O_2 . Reaction with $\cdot\text{NO}_2$ would result in a dinitro adduct and reaction with O_2 would generate a nitroalkylperoxy radical which can undergo further radical chemistry. Electron transfer reactions are probably the most dominant reaction pathway for direct $\cdot\text{NO}_2$ -mediated oxidations in biological systems (not including reactions of $\cdot\text{NO}_2$ -derived species which will be discussed later). Nitrogen dioxide will react reasonably well with, for example, the anions of ascorbate, phenol, or thiols with rate constants of approximately 10^7 – $10^8 \text{ M}^{-1} \text{ s}^{-1}$ to form NO_2^- and the corresponding radical species. The radical generated from the reaction of $\cdot\text{NO}_2$ with phenoxide can either react with another equivalent of $\cdot\text{NO}_2$ or dimerize (Fig. 6) (Prutz *et al.*, 1985).

Consistent with an electron transfer mechanism, the oxidation of phenolic compounds by $\cdot\text{NO}_2$ exhibits a dramatic pH effect. That is, the second order rate constant for the reaction of $\cdot\text{NO}_2$ with, for example, tyrosine is $3.2 \times 10^5 \text{ M}^{-1} \text{ s}^{-1}$ at pH 7.5 and $2.0 \times 10^7 \text{ M}^{-1} \text{ s}^{-1}$ at pH 11.3. Since the pK_a of a phenolic hydroxyl is approximately 10, this indicates an increased rate of reaction for the phenoxide anion. Thiols (or more likely, thiolates) are also oxidized by $\cdot\text{NO}_2$ generating, initially, the corresponding thiyl radical and NO_2^- (Prutz *et al.*, 1985) (Fig. 6). In the presence of excess thiolate, the thiyl radical can, among other reactions, combine with thiolate to form the corresponding disulfide radical anion which is a fairly potent one-electron reductant capable of reducing O_2 to $\text{O}_2^{\cdot-}$ (e.g., see Winterbourn and Metodiewa, 1995). The oxidation of thiolate by $\cdot\text{NO}_2$ has a

second order rate constant of $2.4 \times 10^8 \text{ M}^{-1} \text{ s}^{-1}$ (pH 9.2) and, therefore, is significantly faster than the reaction of $\cdot\text{NO}_2$ with phenoxide. Also, $\cdot\text{NO}_2$ is reported to react with $\text{O}_2^{\cdot-}$ by an electron transfer process to give NO_2^- and O_2 with a second order rate constant of approximately $10^8 \text{ M}^{-1} \text{ s}^{-1}$ (Warneck and Wurzing, 1988).

Dinitrogen Tetroxide, Dinitrogen Trioxide, and Related Species

Since $\cdot\text{NO}_2$ is a free radical, it can further react with other radical species including itself or $\cdot\text{NO}$. The rapid radical–radical combination reaction of two $\cdot\text{NO}_2$ molecules results in the formation of dinitrogen tetroxide (N_2O_4) [reaction (4)]. Due to the delocalization of the unpaired electron, dimerization of $\cdot\text{NO}_2$ can occur in a variety of ways. The most stable structure of N_2O_4 in aqueous solution is generally thought to contain a nitrogen–nitrogen bond (Fig. 7) (other forms that contain an N–O bond between two $\cdot\text{NO}_2$ molecules can exist as well).

In an aqueous environment N_2O_4 is unstable with respect to hydrolysis, which results in the generation of one equivalent each of nitrite (NO_2^-) and nitrate (NO_3^-) [reaction (5)].

Reaction (5) represents the nitrosation (addition of the equivalent of NO^+) of water by N_2O_4 to give NO_2^- . Dinitrogen

Figure 6 The reaction of $\cdot\text{NO}_2$ with phenoxide and thiolate.

Figure 7 Most stable structures of N₂O₄ and N₂O₃. Both molecules are planar, and only one resonance form for each is shown.

tetroxide is, in fact, a generally good nitrosating agent as demonstrated by its efficient reaction with thiols resulting in the generation of *S*-nitrosothiols [reaction (6)] (Oae *et al.*, 1978).

This reaction exemplifies the ability of N₂O₄ to act as a source of nitrosonium ion (NO⁺). In fact, N₂O₄ is reported to be in equilibrium with NO⁺ and NO₃⁻ under a variety of conditions. It is not immediately clear how NO⁺ and NO₃⁻ can be in direct equilibrium with the N–N bridged structure of N₂O₄ shown in Fig. 7 since formation of NO⁺ and NO₃⁻ from O₂N–NO₂ would require not only the cleavage of the N–N bond but also a transfer of an oxygen atom from one nitrogen to the other. However, it should be noted that other structures for the •NO₂ dimer are possible (and may be in equilibrium) which may account for the nitrosating ability of N₂O₄. For example, the N–N bonded species shown in Fig. 7, O₂N–NO₂, may be in equilibrium with an N–O bonded species, ON–ONO₂, and nucleophilic attack on the trivalent nitrogen atom of ON–ONO₂ followed by heterolytic N–O bond cleavage would yield directly the observed nitrosated product and NO₃⁻ (Challis and Kyrtpoulos, 1978). Regardless, the nitrosating ability of N₂O₄ is well established and synthetically useful.

A radical–radical combination reaction between •NO₂ and •NO gives dinitrogen trioxide (N₂O₃) [reaction (7)]. As with •NO₂ dimerization, the most stable structure of N₂O₃ contains an N–N bond (Fig. 7). Dinitrogen trioxide is also unstable in an aqueous system and hydrolyzes to generate two equivalents of NO₂⁻ [reaction (8)]. Like N₂O₄, N₂O₃ not only exists as an N–N bonded species, ON–NO₂, but can also exist as an N–O bonded species, ON–ONO, which may be responsible for most of the nitrosation chemistry (Challis and Kyrtpoulos, 1978). Thus, similar to the reaction of N₂O₄ with water, the reaction of N₂O₃ represents a net nitrosation of water to give NO₂⁻. Nitrosation of other nucleophiles such as thiols can also occur via this chemistry and will be discussed later.

Although oxidation of •NO by O₂ results in •NO₂ formation [reactions (1–3)] and •NO₂ is known to dimerize to N₂O₄ and then hydrolyze to form NO₂⁻ and NO₃⁻ [reactions (4) and

(5)], air oxidation of •NO in an aqueous environment results in the near exclusive generation of NO₂⁻ with little or trace amounts of NO₃⁻. The lack of NO₃⁻ formation indicates that N₂O₄ (the •NO₂ dimerization product) is not generated in appreciable amounts when •NO is air oxidized in water. The absence of N₂O₄ formation when •NO is air oxidized is due to the fact that any •NO₂ formed is rapidly trapped by excess •NO to form N₂O₃ [reaction (7)] which is rapidly hydrolyzed to give exclusively NO₂⁻ [reaction (8)]. Therefore, the levels of •NO₂ under these conditions do not get high enough for the second order dimerization reaction [reaction (4)] to be significant.

The stoichiometric expression for reactions (1)–(3), (7), and (8), the oxidation of •NO by O₂ to NO₂⁻ in an aqueous system, is written as follows:

The rate expression for the loss of •NO from reaction (9) is thus $-d[\text{NO}]/dt = 4k[\bullet\text{NO}]^2[\text{O}_2]$ with $k = 2 \times 10^6 \text{ M}^{-2} \text{ s}^{-1}$ (Ford *et al.*, 1993; Lewis and Deen, 1994). Thus, •NO degradation in an aerobic, aqueous solution is not linear with respect to the •NO concentration. For example, assuming O₂ concentrations around 200 μM, a 10 μM solution of •NO will have degraded to half its original concentration in about 1 minute whereas a 10 nM solution will take over 70 hours to degrade to half its original concentration (note that the term “half-life” is not used in this context since the decomposition kinetics are not first order and therefore the half-life changes with •NO concentration).

Nitrate and Nitrite

The pK_a of nitric acid (HNO₃) is –1.6 and, therefore, the nitrate ion, NO₃⁻, is the near exclusive species present under physiological conditions. Nitrate, though, has little or no physiologically relevant chemistry. However, under certain physiological conditions, NO₂⁻ chemistry can occur. The pK_a of nitrous acid (HNO₂) is 3.3, much higher than that of nitric acid. Nitrous acid exists in equilibrium with N₂O₃ in water (Williams, 1983) [reaction (10)]. Dinitrogen trioxide can be considered to be the anhydride of nitrous acid.

Thus, under slightly acidic conditions, NO₂⁻ can be protonated to generate N₂O₃. The equilibrium constant for reaction (10) ([N₂O₃]/[HNO₂]²) is reported to be $3.03 \times 10^{-3} \text{ M}^{-1}$ (although there is some discrepancy between the older literature and the more recent reports) (Williams, 1983, and references therein). Nevertheless, N₂O₃ is a potent electrophile capable of nitrosating (adding the elements of “NO⁺”) a variety of nucleophiles [as is evidenced by reaction (8) where H₂O serves as the nucleophile]. Consistent with N₂O₃ as the nitrosating agent, the rate expression for the nitrosation of nucleophiles by acidified NO₂⁻ is first order in the nucleophile (Nuc) and first order in N₂O₃, rate = $k[\text{Nuc}][\text{N}_2\text{O}_3]$. The rate of nitrosation of amines by acidified NO₂⁻ can be expressed as rate = $k[\text{amine}][\text{HNO}_2]^2$, again

consistent with N_2O_3 as the nitrosating species. The rate constants for amine nitrosation by N_2O_3 can be quite high (on the order of 10^8 – $10^9 \text{ M}^{-1} \text{ s}^{-1}$). It should be realized, however, that nitrosation by NO_2^- is second order in HNO_2 and would therefore require fairly high concentrations and low acidity to be physiologically relevant. Thiol nitrosation by N_2O_3 may be an important physiological occurrence and will be specifically covered later in the text in a discussion of $\cdot\text{NO}$ –thiol chemistry. Under extremely acidic, nonphysiological conditions, nitrosation of nucleophiles can occur via a process which is first order in HNO_2 . Under these conditions, the nitrosating agent is likely to be either H_2NO_2^+ or NO^+ , both of which will have no appreciable lifetime under physiological conditions.

Of potential physiological and toxicological importance is the reaction of NO_2^- with oxyhemoproteins such as oxyhemoglobin. It has been known for many years that the reaction of NO_2^- with, for example, oxyhemoglobin results in methemoglobin and NO_3^- formation (e.g., Wallace and Caughey, 1975; Doyle *et al.*, 1985; Kosaka *et al.*, 1981). This reaction is multistep, complex, and characterized by a lag phase followed by an autocatalytic phase. The overall mechanism of this reaction is a matter of some speculation although it appears to be generally accepted that the first step involves an electron transfer reaction between NO_2^- and oxyhemoglobin [reaction (11)] (Wallace and Caughey, 1975). This initiation step is slow and most likely accounts for the lag phase of the reaction.

It has been proposed that the $\text{HbFe}^{\text{III}}\text{OOH}$ species depicted in reaction (11) can then react with NO_2^- to also generate $\cdot\text{NO}_2$ and a high valent metaloxo species that further reacts with NO_2^- to give $\cdot\text{NO}_2$ and methemoglobin, HbFe^{III} [reactions (12) and (13)].

Since the process is autocatalytic, there is a requirement that a step which generates one of the products also generates a reactive, “chain carrying” intermediate. This argument has led to the proposal that $\cdot\text{NO}_2$ reacts with oxyhemoglobin to generate the perferryl intermediate of reaction (12) [reaction (14)] (Lissi, 1998).

Although the reaction sequence depicted above accounts for the lag phase and autocatalytic nature of the chemistry, the overall reaction scheme remains speculative and, as yet, unestablished.

The Reaction of $\cdot\text{NO}$ with Superoxide in Aqueous Solution and the Formation of Peroxynitrite ($^-\text{OONO}$)

The one-electron reduction of O_2 results in the generation of $\text{O}_2^{\cdot-}$. The electron configuration for this species is

$\text{KK}(\sigma_x^2)(\sigma_y^2)(\sigma_z^2)(\pi_{xy}^4)(\sigma_z^2)(\pi_{xy}^*)^3$ and therefore $\text{O}_2^{\cdot-}$ possesses an unpaired electron occupying a π^* antibonding orbital. Thus, since both $\cdot\text{NO}$ and $\text{O}_2^{\cdot-}$ both have unpaired electrons, the reaction between them is extremely facile (Blough and Zafirov, 1985) with a rate constant near the diffusion controlled limit [reaction (15)] (Huie and Padmaja, 1993; Goldstein and Czapski, 1995).

In a related reaction, $\cdot\text{NO}$ is also capable of reacting with metal-bound O_2 complexes. For example, oxyhemoglobin and oxymyoglobin react readily with $\cdot\text{NO}$ to give NO_3^- and the oxidized hemoproteins, methemoglobin and metmyoglobin (Doyle and Hoekstra, 1981). The similarity between this reaction and the direct reaction of $\cdot\text{NO}$ with $\text{O}_2^{\cdot-}$ is easily seen if one considers that the O_2 complexes of ferrous hemoglobin (HbFe^{II}) or ferrous myoglobin are probably more accurately depicted as ferric- $\text{O}_2^{\cdot-}$ complexes (i.e., $\text{Hb-Fe}^{\text{III}}-\text{O}_2^{\cdot-}$) [reaction (16)].

Reaction with oxyhemoglobin or oxymyoglobin serves as a very useful assay for $\cdot\text{NO}$ since the conversion of oxyhemoglobin or oxymyoglobin to methemoglobin or metmyoglobin is easily followed by visible spectroscopy (Murphy and Noack, 1994).

The Chemistry of $^-\text{OONO}$

The immediate product from the reaction of $\cdot\text{NO}$ with $\text{O}_2^{\cdot-}$ is $^-\text{OONO}$ [reaction (15)]. The pK_a of HOONO is reported to be 6.8 and, therefore, a significant amount of the protonated species, peroxynitrous acid (HOONO), exists at physiological pH (e.g., see Koppenol *et al.*, 1992). Peroxynitrous acid is a much more potent oxidizing agent than either $\text{O}_2^{\cdot-}$ or $\cdot\text{NO}$ and is capable of carrying out a variety of oxidations. Early reports on the chemical nature of HOONO indicated that it was capable of decomposing via homolytic O–O bond cleavage to generate hydroxyl radical ($\text{HO}\cdot$) and $\cdot\text{NO}_2$ (e.g., Mahoney, 1970). The calculated homolysis enthalpy for the O–O bond predicts a bond dissociation energy of only 22.5 kcal/mol to give the hydroxyl and nitrogen dioxide radicals (Bartberger *et al.*, 1998). Recombination of these two radical species could then result in NO_3^- formation [reaction (17)].

The proposed generation of $\text{HO}\cdot$ and $\cdot\text{NO}_2$ as intermediates in the decomposition of HOONO may account for its oxidizing capability since both species are potent oxidizing agents. The idea that $\text{HO}\cdot$ and $\cdot\text{NO}_2$ are formed as species along the reaction coordinate of HOONO decomposition to NO_3^- has been disputed (e.g., Koppenol *et al.*, 1992; Pou *et al.*, 1995; Shi *et al.*, 1994; Pryor *et al.*, 1996; Lemercier *et al.*, 1995). Therefore, other reactive intermediates or species have been proposed to account for the oxidizing potential of HOONO .

However, numerous reports have indicated that finite amounts of $\text{HO}\cdot$ and $\cdot\text{NO}_2$ may be formed from $\text{}^-\text{OONO}$ decomposition and that at least some of the oxidation chemistry associated with HOONO may be a result of $\text{HO}\cdot$ or $\cdot\text{NO}_2$ generation (e.g., Pfeiffer *et al.*, 1997; van der Vliet *et al.*, 1994; Merenyi and Lind, 1997, 1998). Theoretical studies support the existence of $[\text{HO}\cdot-\cdot\text{NO}_2]$ caged radical pairs as possible intermediates in HOONO decomposition (Houk *et al.*, 1996), a concept previously proposed by others (Pryor and Squadrito, 1995). Although the exact nature of the oxidant(s) formed by HOONO is a matter of some controversy, there is no question that HOONO can serve to oxidize a variety of molecules. For example, HOONO is capable of converting methionine to the corresponding sulfoxide via a two electron oxidation or capable of oxidizing methionine by a single electron resulting in the elimination of ethylene (Pryor *et al.*, 1994). In spite of the oxidizing potential of HOONO , the rate constants for reaction with easily oxidizable substrates like ascorbate monoanion ($k = 2.36 \times 10^2 \text{ M}^{-1} \text{ s}^{-1}$) (Squadrito and Pryor, 1995; Bartlett *et al.*, 1995) or sulfhydryls ($k = 5.9 \times 10^3 \text{ M}^{-1} \text{ s}^{-1}$) (Radi *et al.*, 1991) are surprisingly small.

As indicated above, HOONO is a potent oxidant. However, the conjugate base, $\text{}^-\text{OONO}$, possesses nucleophilic character as evidenced by its ability to react with electrophiles such as carbon dioxide (CO_2) (Lyman and Hurst, 1995; Uppu *et al.*, 1996). The reaction of $\text{}^-\text{OONO}$ with CO_2 is one of the fastest known reactions for $\text{}^-\text{OONO}$ ($k = 3 \times 10^4 \text{ M}^{-1} \text{ s}^{-1}$). In fact, in a physiological milieu, one of the predominant fates of $\text{}^-\text{OONO}$ generation is likely to be reaction with CO_2 due to the relatively high rate constant and the high concentration of CO_2 ($>1 \text{ mM}$ in plasma). The immediate reaction product from the $\text{}^-\text{OONO}/\text{CO}_2$ reaction is nitrosoperoxy carbonate [reaction (18)].

Like HOONO , nitrosoperoxy carbonate is inherently unstable and spontaneously rearranges to the nitrocarbonate anion which can then hydrolyze to generate NO_3^- and bicarbonate (HCO_3^-) [reactions (19) and (20)]. Since HCO_3^- is in equilibrium with CO_2 and H_2O , the process is catalytic with respect to CO_2 .

Thus, CO_2 can serve as a catalyst for the degradation of $\text{}^-\text{OONO}$ to NO_3^- . Similarly, theoretical studies have postulated that ketones can catalyze the conversion of $\text{}^-\text{OONO}$ to NO_3^- (Bartberger *et al.*, 1998).

Instead of acting merely as a degradation catalyst, CO_2 can also serve to activate $\text{}^-\text{OONO}$ as a nitrating agent. For example, the ability of $\text{}^-\text{OONO}$ to nitrate aromatic rings is significantly increased in the presence of CO_2 (Gow *et al.*, 1996; Denicola *et al.*, 1996). However, other oxidations performed by $\text{}^-\text{OONO}$ (i.e., thiol oxidation, benzoate

hydroxylation, etc.) are inhibited by the presence of CO_2 (Denicola *et al.*, 1996; Zhang *et al.*, 1997).

The potential physiological generation of $\text{}^-\text{OONO}/\text{HOONO}$ results from the rapid reaction of $\text{O}_2^{\cdot-}$ with $\cdot\text{NO}$ [reaction (15)], both known to be generated in significant amounts under certain pathophysiological conditions. However, HOONO can react further with either $\cdot\text{NO}$ or $\text{O}_2^{\cdot-}$ to generate, among other things, $\cdot\text{NO}_2$ [reactions (21) and (22)] (Miles *et al.*, 1996).

Thus, the fate/lifetime of $\text{}^-\text{OONO}/\text{HOONO}$ may also depend on the “flux” of the two precursors, $\cdot\text{NO}$ and $\text{O}_2^{\cdot-}$.

Due to the potential relevance of $\text{}^-\text{OONO}$ to biological systems and reports implicating it as a major factor in a variety of pathophysiological processes, the chemistry and biology of $\text{}^-\text{OONO}$ has been the subject of intense investigation. The treatment of this topic herein is only meant as an introduction to this work and is not intended to be either comprehensive or exhaustive. For a more detailed treatment of this subject the reader is referred to any one of a number of excellent reviews (Pryor and Squadrito, 1995; Beckman *et al.*, 1994; Edwards and Plumb, 1994).

The Free-Radical Chemistry of $\cdot\text{NO}$

As indicated above, $\cdot\text{NO}$ reacts rapidly via simple radical–radical combination reactions with species possessing unpaired electrons such as $\cdot\text{NO}_2$, O_2 , and $\text{O}_2^{\cdot-}$. The ability of $\cdot\text{NO}$ to “quench” other radical species also allows it to terminate radical chain reactions. A good example of this phenomenon is the effect $\cdot\text{NO}$ has on the O_2 -dependent oxidation of lipids (e.g., Wink *et al.*, 1993; Hogg *et al.*, 1993; Rubbo *et al.*, 1994, 1995; Struck *et al.*, 1995). Due to the fact that many lipids contain “activated” allylic C–H bonds, they are susceptible to oxidative damage. Lipid peroxidation results from the net abstraction of an allylic hydrogen atom of the unsaturated fatty acid (Lipid–H) by an initiating radical species ($\text{X}\cdot$) to generate a lipid radical (Lipid \cdot) [reaction (23)]. The lipid radical then reacts with O_2 to generate an alkylperoxy radical (Lipid– $\text{OO}\cdot$) which can further react with another lipid to form another lipid radical that can also react with O_2 [reactions (24–25)]. These two reactions represent chain propagating steps.

The outcome of this sequence of reactions is that a single initiating event can lead to the destruction/modification of numerous lipid molecules which can result in a loss of

membrane integrity. Lipid peroxidation can be avoided or limited either by inhibiting the generation of the initiating species “X•” [reaction (23)] or by quenching one of the chain carrying radical intermediates, Lipid–OO• or Lipid• [reactions (24) and (25)]. Nitric oxide is known to limit lipid peroxidation by acting as a chain terminating species [e.g., reaction (26)].

Further, •NO has been reported to inhibit the generation of chain initiating species by altering the reactivity of metals known to serve as catalysts for their generation (this aspect of •NO chemistry will be addressed in detail later in the discussion of •NO and metals) (for a general review on •NO and free radical biology, see Rubbo *et al.*, 1996).

Unlike other radical species such as •NO₂, halogen atoms, or HO•, •NO does not readily abstract hydrogen atoms (S_H2 reaction) or add to unsaturated bonds. The inability of nitric oxide to serve as an oxidizing agent (i.e., via H atom abstraction) can be inferred from its low reduction potential ($E^\circ = 0.39$ V for the NO/⁺NO couple and -0.35 V for the NO/[•]NO couple) (Stanbury, 1989). For comparison, the reduction potentials for •NO₂, HO•, F•, and Cl• are 1.04, 1.9, 3.6, and 2.41 V, respectively. There are, however, some instances where •NO has been proposed to abstract H atoms. For example, the reaction of •NO with hydroxylamine (NH₂OH) gives as final products dinitrogen (N₂), nitrous oxide (N₂O), and water [reaction (27)].

The first step of this complex reaction appears to involve the abstraction of a hydrogen atom from the nitrogen of hydroxylamine to generate nitroxyl (HNO) and the corresponding nitrogen-centered radical species (Bonner and Wang, 1986).

The Reactions of •NO with Metals

Nitric oxide is capable of serving as a ligand in a variety of metal complexes, and the coordination chemistry of •NO with metals has been examined extensively (for comprehensive reviews see Richter-Addo and Legzdins, 1992; McCleverty, 1979; Eisenberg and Meyer, 1975). Nitrosonium ion (NO⁺) is isoelectronic with carbon monoxide (CO), therefore many metals that form carbonyl (CO) complexes are also capable of forming isoelectronic and isostructural nitrosyl (•NO) complexes. However, •NO differs from CO as a metal ligand in that it can adopt two different binding geometries reflecting different metal–NO bonding interactions. The geometry of the metal–NO bond can either be linear (Fig. 8A), or bent (Fig. 8B).

The linear geometry is the most common bonding mode for metal nitrosyls and, in this situation, the net bonding interaction between the metal and •NO consists of both σ donation from •NO to the metal and π backbonding from occupied *d* orbitals of proper symmetry on the metal to the

π^* antibonding orbital on •NO (Fig. 8A). In the bent geometry, the metal can be envisioned to donate an electron to •NO to form NO[−], which then binds the metal in a σ interaction. This leaves an electron pair localized in an *sp*² orbital on the nitrogen atom of the ligand. For “electron counting” purposes the nitrosyl ligand in the linear bonding complexes is considered to be nitrosonium ion, NO⁺, and in the bent complexes, nitroxyl, NO[−]. That is, in the linear bonding geometry, •NO is envisioned to donate an electron to the metal prior to bonding and thus it is formally NO⁺. In the bent geometry, the metal can be envisioned to first donate an electron to •NO, giving NO[−], which then binds the metal. Using this formalism, •NO is considered to be a three-electron donor (one-electron donation to the metal to make NO⁺ and two-electron donation to form the M–NO bond) in the linear bonding mode, but a one-electron donor (two-electron donation to form the M–NO bond minus one electron donated from the metal to •NO) in the bent geometry. It should be noted that this assignment is merely a formalism for counting electrons in these complexes and does not always reflect the chemistry or properties of the nitrosyl ligand.

The ability of •NO to bind metals via the two modes described above makes it an “amphoteric” ligand (e.g., see Collman *et al.*, 1987). The conversion of a linear to bent bonding geometry in a metal–nitrosyl complex is equivalent to oxidizing the metal since the bent geometry requires a formal donation of electrons from the metal to the nitrosyl ligand. This may change the overall coordination geometry of the metal. Although biological relevance of this phenomenon has not been reported, the amphoteric nature of •NO binding to metals is rare among all ligands and would certainly allow unique interactions with metalloproteins not available to other biologically relevant diatomic ligands (CO, O₂, CN[−], etc.).

Coordination of •NO to a metal as either “NO⁺” or “NO[−]” may predict that metal-bound nitrosyls can be either electrophilic or nucleophilic. That is, •NO ligands bound in a linear fashion to metals might be expected to be subject to nucleophilic attack whereas •NO bound in a bent fashion might be susceptible to reaction with electrophiles. Although this type of argument is not rigorous since the assignment of the ligands as “NO⁺” and “NO[−]” is only a formalism for accounting for electrons, metal bound nitrosyls exhibit both electrophilic as well as nucleophilic character (Cotton and Wilkinson, 1988).

Due to the fact that •NO is more electronegative than CO and thus a better electron acceptor, it can more efficiently backbond with occupied *d* orbitals on metals. A major portion of the strength of many metal–NO bonds is due to the backbonding phenomenon (Fig. 8A), and since this type of bonding is more prevalent with •NO compared to CO, the metal–NO bond is generally stronger than the metal–CO bond. Thus, •NO is typically a better (more stable) ligand for backbonding metals compared to CO. A corollary to this idea is that complexation of •NO to metals weakens the N–O bond since electrons from the metal are being transferred into an •NO antibonding orbital.

Figure 8 (A) Linear geometry (arrows depict bonding interactions) and (B) bent geometry for M-nitrosyl bond. M = metal ion.

As indicated above, the bonding of $\cdot\text{NO}$ to metals can be envisioned to result in the formation of an electropositive nitrosyl ligand [reaction (28)].

Formally, this can be thought of as an internal electron transfer from $\cdot\text{NO}$ to the metal to give a complex that consists of a reduced metal and an NO^+ ligand. Although it is unwise to assume that this is always the bonding interaction between $\cdot\text{NO}$ in metal complexes (see above), there are cases where the binding to metals makes $\cdot\text{NO}$ susceptible to nucleophilic attack. For example, ligation of $\cdot\text{NO}$ to a synthetic ferric porphyrin species, tetraphenylporphyriniron(III) chloride ($\text{Fe}^{\text{III}}\text{TPP}\text{Cl}$), in the presence of a protic solvent such as methanol or water results in the eventual formation of a ferrous nitrosyl adduct (Wayland and Olson, 1974; Chien, 1969). The mechanism for this reductive nitrosylation is multistep and is shown below [reactions (29–31)].

The ability of ferriporphyrins to activate $\cdot\text{NO}$ to be a nitrosating agent for nucleophilic species has been further demonstrated with hemoproteins such as myoglobin and catalase, whereby addition of $\cdot\text{NO}$ to the ferric form of these proteins led to the nitrosation of, for example, phenol (Wade and Castro, 1990). This chemistry was further extended to include nitrosation of nucleic acids resulting in the conversion of cytosine to uracil (Castro and Bartnicki, 1994). It also appears that other nonheme metal ion complexes ligate and activate $\cdot\text{NO}$ in a similar manner (Gwost and Caulton, 1973).

Nitric oxide can also perform similar chemistry with certain cupric complexes. For example, it has been reported that synthetic cupric complexes with relatively high reduction potentials can be reduced by bound $\cdot\text{NO}$ via an inner-sphere charge transfer mechanism. Nucleophilic attack by metha-

nol, for example, on the bound nitrosyl ligand (or nitroso-nium ligand) ($\text{LCu}^{\text{I}}-\text{NO}^+$) results in the generation of the cuprous complex (LCu^{I}) and the nitrite ester of methanol (MeONO) (Tran *et al.*, 1998) [reactions (32) and (33)].

It has been proposed that the ability of $\cdot\text{NO}$ to bind and reduce redox active metals, such as iron, may indirectly lead to the generation of oxygen-derived free radical species via the Fenton reaction (Farias-Eisner *et al.*, 1996) [reaction (34)].

That is, $\cdot\text{NO}$ can reduce ferric ion, Fe^{III} (under slightly acidic conditions), to ferrous ion, Fe^{II} , which in the presence of hydrogen peroxide (H_2O_2) can lead to the generation of potent oxidants such as $\text{HO}\cdot$. However, others have reported that $\cdot\text{NO}$ actually inhibits this chemistry since it can bind Fe^{II} complexes, forming the ferrous nitrosyl complex, which is unable to catalyze reaction (34) and/or changes the course of the reaction giving other, nonoxidizing products [reaction (35)] (e.g., Kanner *et al.*, 1991, 1992; Kanner, 1996, and references therein).

Thus, $\cdot\text{NO}$ can act as an antioxidant by serving as a radical chain-terminating species [reaction (26)] or by altering the chemistry of catalytic metal species. However, depending on the conditions of the reaction (i.e., pH, ligand system, $\cdot\text{NO}$ concentration, etc.), it is conceivable that $\cdot\text{NO}$ can serve as a pro-oxidant capable of activating catalytic metals that generate reactive oxygen species.

The coordination of $\cdot\text{NO}$ to iron hemoproteins is an important aspect of its physiological utility. In fact, $\cdot\text{NO}$ is an extremely good ligand for ferrous hemes and, unlike other simple diatomic ligands such as O_2 and CO , binds ferric hemes as well (although the affinity of $\cdot\text{NO}$ to ferrous hemes is significantly greater) (e.g., Hoshino *et al.*, 1993). One of

the most important functions of biological $\cdot\text{NO}$ is to serve as an activator of the iron heme-containing enzyme guanylate cyclase (Ignarro, 1989). However, other biologically relevant and similar ligands such as O_2 and CO also bind iron hemoproteins and yet they do not possess the unique biological activity associated with $\cdot\text{NO}$. Thus, the nature of the interaction between $\cdot\text{NO}$ and hemoproteins is distinct from that of other simple diatomic ligands. One of the ways in which $\cdot\text{NO}$ is distinct from, for example, O_2 and CO , is that its coordination to a ferrous hemoprotein labilizes the trans axial ligand (Fig. 9) (Traylor and Sharma, 1992).

In the case of guanylate cyclase, the trans axial ligand is an imidazole moiety (from a histidine) which, after $\cdot\text{NO}$ assisted release, may serve to increase the catalytic activity of the enzyme (Traylor *et al.*, 1993).

The kinetics of $\cdot\text{NO}$ binding to iron hemoproteins are highly dependent on both the oxidation state and coordination environment of the iron center (Hoshino *et al.*, 1993). For example, the association rate constant for $\cdot\text{NO}$ binding to a synthetic ferric heme, $\text{Fe}^{\text{III}}\text{TPPS}$ (TPPS, *meso*-tetrakis (*p*-sulfonatophenyl)porphyrin), is $7.2 \times 10^5 \text{ M}^{-1} \text{ s}^{-1}$ and the rate constant for dissociation is $6.8 \times 10^2 \text{ s}^{-1}$. On the other hand, $\cdot\text{NO}$ irreversibly binds to the ferrous form, $\text{Fe}^{\text{II}}\text{TPPS}$, with a rate constant of $1.8 \times 10^9 \text{ M}^{-1} \text{ s}^{-1}$. Metmyoglobin (MbFe^{III}) binds $\cdot\text{NO}$ with a rate constant of $1.9 \times 10^5 \text{ M}^{-1} \text{ s}^{-1}$ and has a low rate constant of 13.6 s^{-1} for the reverse reaction. Myoglobin (MbFe^{II}) itself binds $\cdot\text{NO}$ irreversibly with a rate constant of $1.7 \times 10^7 \text{ M}^{-1} \text{ s}^{-1}$.

Ferric cytochrome *c* binds $\cdot\text{NO}$ with a rate constant of $7.2 \times 10^2 \text{ M}^{-1} \text{ s}^{-1}$ and $\cdot\text{NO}$ dissociates with a rate constant of $4.4 \times 10^{-2} \text{ s}^{-1}$. Reduced ferrous cytochrome *c* has association and dissociation rate constants of $8.3 \text{ M}^{-1} \text{ s}^{-1}$ and $2.87 \times 10^{-5} \text{ s}^{-1}$, respectively. Note that the rate of binding for the ferrous species is much lower than the rate for binding of ferric cytochrome *c*, but the opposite is true for myoglobin and FeTPPS .

The reaction of $\cdot\text{NO}$ with iron-sulfur (Fe-S) centers has received significant attention since this appears to be an interaction of physiological importance (e.g., Hibbs *et al.*, 1988). Generally, $\cdot\text{NO}$ is able to disrupt Fe-S clusters, releasing iron in the form of a dinitrosyl-iron-dithiol complex (e.g., Drapier, 1997; Kennedy *et al.*, 1997). The mechanistic intricacies of this interaction are not yet fully established.

Figure 9 Labilization of trans axial ligand, X, from ferrous heme by coordination of $\cdot\text{NO}$.

The Reaction of $\cdot\text{NO}$ and $\cdot\text{NO}$ -Derived Species with Thiols

The physiological chemistry of thiols is intimately associated with the physiological chemistry of $\cdot\text{NO}$. As one of the premier nucleophilic species in biological systems, thiols can react with electrophilic nitrogen oxide species derived from $\cdot\text{NO}$. For example, air oxidation of $\cdot\text{NO}$ results in the formation of the electrophilic nitrosating species, N_2O_3 [reactions (1–3) and (7), above]. Nitrosation of thiols by N_2O_3 is facile and results in the formation of an *S*-nitrosothiol (RS-NO) [reaction (36)].

Thiol nitrosation may also occur via the intermediacy of a ferric heme nitrosyl species (or depicted below as a ferrous nitrosonium species) in a similar manner to that shown in reaction (30) [reaction (37)] (Wade and Castro, 1990).

Interestingly, $\cdot\text{NO}$ will also react with thiols under anaerobic conditions. Early studies of this reaction by Pryor and co-workers indicated that thiols (or more likely thiolates, RS^-) will react with $\cdot\text{NO}$ to form intermediates which further decompose to generate N_2O , H_2O , and the corresponding disulfide (Pryor *et al.*, 1982) [reaction (38)].

The mechanism for reaction (38) has been postulated to occur via initial nucleophilic attack onto the electrophilic nitrogen atom of $\cdot\text{NO}$ by thiolate to form an adduct (RS-N-OH) that further reacts with another $\cdot\text{NO}$ to generate an intermediate species which then decomposes spontaneously to give the observed products (Fig. 10) (DeMaster *et al.*, 1995).

Thus, $\cdot\text{NO}$ can directly oxidize thiols to the corresponding disulfides or can indirectly oxidize thiols to *S*-nitrosothiols via intermediates such as N_2O_3 or metal nitrosyl species.

S-Nitrosothiols are capable of releasing $\cdot\text{NO}$ in the presence of cuprous ion [reaction (39)] (e.g., Williams, 1996; Dicks *et al.*, 1996).

Photolytic homolysis of the RS-NO bond generating both $\cdot\text{NO}$ and the corresponding thiyl radical is also possible and is an issue when working with *S*-nitrosothiols.

S-Nitrosothiols can also undergo transnitrosation reactions whereby the nitroso function is transferred from one thiol to another via nucleophilic attack on the nitrogen atom of the *S*-nitrosothiol [reaction (40)] (e.g., see Barnett *et al.*, 1994a,b).

Figure 10 Possible mechanism for the O_2 -independent oxidation of RSH.

Alternatively, the thiol can react at the sulfur atom of the S-nitrosothiol which would generate the disulfide and HNO [reaction (41)] (e.g., Arnelle and Stamler, 1995; Wong *et al.*, 1998).

Further reaction of thiols with HNO is possible (and will be discussed later).

Reduced $\cdot\text{NO}$ Species

Except for HNO/NO^- , most all of the $\cdot\text{NO}$ -derived species mentioned thus far are oxidized with respect to $\cdot\text{NO}$ (see Fig. 4). It appears, however, that biological metabolism of $\cdot\text{NO}$ can lead to reduced as well as oxidized nitrogen species. Already mentioned is the possible generation of HNO from degradation of S-nitrosothiols [reaction (41)]. Other studies have alluded to possible physiological generation of HNO and other reduced species (e.g., Singh *et al.*, 1996; Hobbs *et al.*, 1994; Schmidt *et al.*, 1996). Thus, it is worthwhile to briefly describe the chemistry of species that are reduced relative to $\cdot\text{NO}$.

The Chemistry of HNO

Compared to its redox partners, the physiological/bioinorganic chemistry of HNO has been studied much less (for a review on the basic inorganic chemistry of HNO and related species, see Bonner and Hughes, 1988). One reason for this may be due to the metastable nature of HNO. This lack of inherent stability stems from its self-reactivity, that is, one HNO molecule can react with another to initially give hyponitrous acid, which can then dehydrate to give nitrous oxide (N_2O) [reaction (42)]. Thus, detection of N_2O in chemical studies is often used as an indication of HNO intermediacy (although this is not a rigorous proof; e.g. see Fig. 10). The overall rate constant for the dimerization–dehydration process is extremely high (Bazylinski and Hollocher, 1985a).

In spite of the high rate constant, N_2O formation via reaction (42) might be extremely limited in biological systems. This is due to the fact that reaction (42) is second order in HNO, and HNO dimerization competes with other biologically relevant HNO reactions.

The potential physiological importance of HNO in mammalian systems has only recently been recognized; hence, past interest in its bioinorganic chemistry has been limited (although much of the basic inorganic chemical properties of HNO has been elucidated). The $\text{p}K_a$ of HNO generated by pulse radiolysis is reported to be 4.7 (Gratzel *et al.*, 1970). However, recent calculations indicate that this value may not be correct and the $\text{p}K_a$ may be considerably higher (between 7 and 8) (K. Houk, personal communication, 2000). Regardless, HNO can exist in both protonated and unprotonated forms, and the chemistry of both is possible in aqueous systems. Nitroxyl anion is isoelectronic with O_2 and can therefore exist in either the ground state triplet ($^3\text{NO}^-$) or the excited singlet ($^1\text{NO}^-$) spin state. As with O_2 , the reaction chemistry of NO^- will be highly dependent on its spin state (discussed later). The reduction potential for the couple $\cdot\text{NO}/^1\text{NO}^-$ is -0.35 V , and for $\cdot\text{NO}/^3\text{NO}^-$ is 0.39 V (Stanbury, 1989). Singlet NO^- is, therefore, a much better reducing agent than the triplet form.

Besides its propensity to dimerize and generate N_2O [reaction (42)], NO^- also reacts with its one-electron oxidation product, $\cdot\text{NO}$, to generate N_2O_2^- [reaction (43)] (Gratzel *et al.*, 1970; Seddon *et al.*, 1973). This species is unstable and can either react with another $\cdot\text{NO}$ to give N_3O_3^- [reaction (44)] or it is proposed that it may spontaneously decompose to generate $\text{HO}\cdot$ and N_2O [reaction (45)] (Seddon *et al.*, 1973). N_3O_3^- will decompose to N_2O and NO_2^- [reaction (46)] (Gratzel *et al.*, 1970; Seddon *et al.*, 1973). Thus, at relatively high $\cdot\text{NO}$ concentrations N_2O_2^- will be trapped by $\cdot\text{NO}$ to form N_3O_3^- , but at relatively low $\cdot\text{NO}$ concentrations the rate of N_2O_2^- trapping by $\cdot\text{NO}$ is slow, and spontaneous decomposition of N_2O_2^- to N_2O and $\text{HO}\cdot$ may compete. It should be noted that the generation of $\text{HO}\cdot$ from the decomposition of N_2O_2^- has not been unequivocally demonstrated. It was postulated on the basis of kinetic studies performed at low $\cdot\text{NO}$ concentrations that indicated the existence of a decomposition pathway for N_2O_2^- competing with reaction

(44) (Seddon *et al.*, 1973). Thus, further chemical verification of reaction (45) is needed.

The reaction of $\cdot\text{NO}$ with NO^- [reaction (43)] is particularly fast, as indicated by the large rate constant. Thus, NO^- is a good trap for $\cdot\text{NO}$ and may attenuate or completely change its physiological actions.

As indicated by the negative reduction potential for the NO/NO^- couple ($E^\circ = -0.35 \text{ V}$), singlet NO^- can act as a one-electron reducing agent. An example of this is represented by the ability of NO^- to reduce the cupric form of the enzyme, superoxide dismutase (SODCu^{II}), to the cuprous form (SODCu^{I}) (Murphy and Sies, 1991; Fukuto *et al.*, 1993; Hobbs *et al.*, 1994) [reaction (47)].

In these studies, the source of NO^- dictated that its spin state be a singlet and, therefore, highly reducing. Thus, in the presence of a one-electron oxidizing species, NO^- can be easily converted to $\cdot\text{NO}$, resulting in an environment where both $\cdot\text{NO}$ and NO^- exist. Due to the rate of reaction (43) and the postulated existence of reaction (45), mixtures of NO^- and $\cdot\text{NO}$ may lead to the generation of the potent and indiscriminate oxidizing agent, $\text{HO}\cdot$.

Nitroxyl can also react with oxidized hemoproteins such as methemoglobin or metmyoglobin to generate the reduced ferrous nitrosyl adducts ($\text{HbFe}^{\text{II}}-\text{NO}$) (Bazylinski and Hollocher, 1985b) [reaction (48)].

As indicated earlier in this chapter, the metal–nitrosyl bond can be especially strong; thus the $\text{Fe}^{\text{II}}-\text{NO}$ complex can be extremely stable.

Nitroxyl is also electrophilic, as evidenced by its reaction with thiols to generate an *N*-hydroxysulfenamide [reaction (49)] (Doyle *et al.*, 1988).

This intermediate can react further with excess thiol to give hydroxylamine and the corresponding disulfide [reaction (50)].

Alternatively, the *N*-hydroxysulfenamide can rearrange to generate a sulfinamide (Fig. 11) (Wong *et al.*, 1998).

Since the *N*-hydroxysulfenamide is a common intermediate in the generation of both the disulfide and sulfinamide, the predominance of one product over the other will undoubtedly be a function of the thiol:HNO ratio. That is, at a high thiol:HNO ratio, it may be expected that reaction (50), generation of the disulfide and NH_2OH , will predominate since a second thiol is required to react with the *N*-hydroxysulfenamide. However, at a low thiol:HNO ratio, sulfinamide formation would predominate. Significantly, disulfide formation is physiologically reversible since there are a variety of reductases capable of converting disulfides back to the corresponding thiols. Sulfinamide formation, however, may represent irreversible thiol modification since there are, to date, no reported physiological systems capable of reducing this functional group.

Another example of the electrophilic nature of HNO can be seen in its reaction with olefinic species. In the singlet spin state, HNO can undergo reactions comparable to that observed for singlet oxygen ($^1\text{O}_2$). For example, HNO reacts with 1,3-dienes by a 4 + 2 cycloaddition and can react with olefins in an “ene-like” reaction (Fig. 12) (Ensley and Mahadevan, 1989).

It should be noted that HNO has a possible isomer, NOH. This species has a triplet ground state and has never been observed directly. Moreover, calculations indicate that HNO is the thermodynamically favored isomer (Gallup, 1975). Thus, NOH generation is rare and, in fact, has only been reported to occur in the photolysis of the HNO donor molecule, Angeli's salt (Donald *et al.*, 1986) and in the thermal reaction of $\cdot\text{NO}$ with NH_2OH (Bonner and Wang, 1986).

HNO/ O_2 Chemistry

Very little is understood about the interaction of HNO and O_2 . Most studies of HNO, using HNO donors, were carried out under strict anaerobic conditions precluding any HNO– O_2 chemistry. One previous report, however, indicated that HNO will react with O_2 since a decomposing solution of the HNO donor, Angeli's salt, was found to consume O_2 (Fukuto *et al.*, 1993). Moreover, it was observed that the reaction of HNO with O_2 results in the generation of H_2O_2 , indicating that O_2 is capable of accepting an electron from HNO/ NO^- . The reaction of NO^- with dioxygen is expected to be highly dependent on its spin state. Most of the reports on HNO chemistry involve HNO donor molecules

Figure 11 Mechanism of sulfinamide formation from the reaction of HNO with thiols.

Figure 12 (A) Reaction of HNO with a diene by a 4 + 2 cycloaddition reaction and (B) HNO reaction with an olefin by an ene-type reaction.

that generate the singlet species. It has been reported that singlet NO^- generated *in situ* does not react at an appreciable rate with O_2 to form peroxynitrite ($^-\text{OONO}$) (Donald *et al.*, 1986) (although this certainly does not preclude reaction of HNO with O_2 to give other products). However, *in situ* generated triplet NO^- (via photolysis of the HNO donor molecule, Angeli's salt) has been reported to react with O_2 to give peroxynitrite ($^-\text{OONO}$) (Donald, *et al.*, 1986) [reaction (51)].

The reaction of triplet NO^- with O_2 is reminiscent of and isoelectronic with the well-known reaction between $\cdot\text{NO}$ and superoxide ($\text{O}_2^{\cdot-}$), which also generates $^-\text{OONO}$ [reaction (15)]. Thus, the likelihood of $^-\text{OONO}$ generation from NO^- in an aerobic environment will be a function of the spin state of NO^- .

HNO Donors

HNO is typically generated from precursor molecules due to its self-reactivity [reaction (42)]. Perhaps the best studied and most utilized HNO donor is sodium trioxodinitrate ($\text{Na}_2\text{N}_2\text{O}_3$), better known as Angeli's salt (Bonner and Hughes, 1988, and references cited therein). This inorganic salt is fairly stable under basic conditions but will spontaneously release HNO between pH 4 and 8 with a first order rate constant of $4.6 \times 10^4 \text{ s}^{-1}$ [reaction (52)] (Bonner and Ravid, 1975).

The species released thermally from Angeli's salt is singlet HNO, as evidenced by its lack of reactivity with ground state O_2 (Donald *et al.*, 1986). A number of laboratories have used Angeli's salt in examining the chemistry of HNO; indeed, much of the HNO chemistry discussed above was delineated using Angeli's salt as the source of HNO.

Another possible way of generating HNO is via the decomposition of compounds with the *N*-hydroxysulfonamide functional group. The best known of these is *N*-hydroxybenzenesulfonamide or Piloty's acid [$\text{C}_6\text{H}_5\text{S}(\text{O})_2\text{NHOH}$], which, under basic conditions, disproportionates to HNO and benzenesulfinic acid [$\text{C}_6\text{H}_5\text{S}(\text{O})\text{O}^-$] [reactions (53) and (54)].

As is the case with Angeli's salt, the spin state of NO^- generated from Piloty's acid is singlet (Bonner and Ko, 1992).

Other Reduced $\cdot\text{NO}$ Species; NH_2OH

Reduction of $\cdot\text{NO}$ by three electrons (or two-electron reduction of HNO) results in the formation of hydroxylamine (NH_2OH), and further reduction by two electrons gives ammonia (NH_3) (Fig. 4). As previously indicated, HNO can be reduced by thiols to form NH_2OH via reactions (49) and (50). The physiologically relevant chemistry of NH_2OH includes its ability to serve as a reducing agent and nucleophile. The ability of NH_2OH to serve as a reducing agent is exemplified by its reactions with hemoproteins. For example, reaction of NH_2OH with oxyhemoglobin results in the initial formation of the hydronitroxide radical ($\text{NH}_2\text{O}\cdot$) and the corresponding peroxide intermediate ($\text{HbFe}^{\text{III}}-\text{OOH}$) [reaction (55)] (Stolze and Nohl, 1989; Stolze *et al.*, 1996).

The $\text{NH}_2\text{O}\cdot$ radical is unstable and may further react via a number of pathways depending on the conditions. For example, it may react with itself in a second order process to generate N_2 and H_2O (Stolze and Nohl, 1989) [reaction (56)].

[The physiological relevance of reaction (56) may be precluded by the second order dependence on $\text{NH}_2\text{O}\cdot$, however.] The putative and fleeting ferric peroxide intermediate in reaction (55) has been proposed to either release H_2O_2 or decompose to generate a high valent oxo intermediate which can perform further oxidation chemistry (Stolze and Nohl, 1989, 1990; Stolze *et al.*, 1996). Regardless, it is apparent that NH_2OH is capable of acting as a reducing agent (or H-atom donor) for oxygen bound hemoproteins. Hydroxylamine is also able to reduce ferric hemes. For example, reaction of NH_2OH with methemoglobin under anaerobic conditions has been proposed to generate deoxyhemoglobin via reaction (57) (Bazylinski *et al.*, 1987).

It has also been reported that NH_2OH can oxidize deoxyhemoglobin, under anaerobic conditions, to generate methemoglobin [reaction (58)] (Bazylinski *et al.*, 1987).

The combination of reactions (57) and (58) indicates that hemoglobin can act as a catalyst for the disproportionation of NH_2OH to N_2 and NH_3 [reaction (59)].

Along with its ability to serve as a reducing agent, due to a phenomenon known as the α effect, hydroxylamine is also a potent nucleophile (much better than, e.g., ammonia). This effect results from the juxtaposition of the nucleophilic lone pair of electrons on the nitrogen atom and the lone pairs on the adjacent oxygen atom. Thus, NH_2OH will react with a variety of electrophiles, such as aldehydes and ketones, which are converted to the corresponding oximes.

Summary

The chemistry of $\cdot\text{NO}$ and $\cdot\text{NO}$ -derived species consists of numerous interrelated and interdependent processes. This is best exemplified by the scheme shown in Fig. 13 where some of the more important and previously discussed aspects of the physiological chemistry of $\cdot\text{NO}$ are depicted. As is evident from Fig. 13, the chemistry of $\cdot\text{NO}$ and related nitrogen oxides will be a function of their concentration and environment. For example, many of the pathways depicted have greater than first order dependencies on $\cdot\text{NO}$ concentration and, therefore, are not as likely to occur at low concentrations as those with a first order dependence on $\cdot\text{NO}$. Other reaction pathways involve participation of other chemical entities such as O_2^- or thiols that may have widely varying physiological concentrations. To be sure, Fig. 13 is by no means intended to be a comprehensive depiction of physiological nitrogen oxide chemistry, and many of the processes have been simplified for the sake of convenience. Furthermore, it is not the intent of this chapter to indicate that all the intricacies of nitrogen oxide physiological chemistry are currently understood. On the contrary, this topic remains a vital and active field, and it is likely that numerous other important reactions and/or metabolic pathways for $\cdot\text{NO}$ and related nitrogen oxides will be demonstrated in the future. What is clear, however, is that the chemistry and physiology of $\cdot\text{NO}$ and related nitrogen oxides are intimately linked. The physiological importance of nitrogen oxides will undoubtedly lead to the discovery (or rediscovery) of new aspects of nitrogen oxide chemistry.

THE MULTIPLE EFFECTS OF NO IN BIOLOGICAL SYSTEMS HAVE RESULTED IN INTENSE INVESTIGATION INTO THE MECHANISMS OF NO-MEDIATED EVENTS. THE CHEMISTRY OF NO IS THE PRIMARY DETERMINANT OF ITS BIOLOGICAL PROPERTIES. HOWEVER, NOT ALL THE REACTIONS OF NO THAT CAN BE PERFORMED IN THE TEST TUBE ARE PERTINENT *IN VIVO*. THIS CHAPTER PROVIDES A GUIDE THROUGH THE DIVERSE REACTIONS OF NO IN BIOLOGICAL SYSTEMS. THE SCHEME OF THE CHEMICAL BIOLOGY OF NO DIVIDES THE REACTIONS OF NO INTO THE TWO CATEGORIES OF DIRECT AND INDIRECT EFFECTS. DIRECT EFFECTS ARE DEFINED AS THOSE REACTIONS THAT ARE FAST ENOUGH TO OCCUR BETWEEN NO AND SPECIFIC BIOLOGICAL TARGETS. INDIRECT EFFECTS DO NOT INVOLVE NO BUT RATHER ARE MEDIATED BY REACTIVE NITROGEN OXIDE SPECIES FORMED FROM THE REACTION OF NO WITH EITHER OXYGEN OR SUPEROXIDE. THESE SPECIES CAN MEDIATE EITHER NITROSATIVE OR OXIDATIVE STRESS. THIS REPORT DISCUSSES ASPECTS OF THE CHEMICAL BIOLOGY OF NO RELATING TO BIOLOGICAL MOLECULES SUCH AS GUANYLATE CYCLASE, CYTOCHROME P-450, NITRIC OXIDE SYNTHASE, CATALASE, AND DNA AND EXPLORES THE POSSIBLE ROLES NO PERFORMS IN DIFFERENT BIOLOGICAL SITUATIONS.

Introduction

Nitric oxide (NO) is an endogenous mediator of numerous physiological processes that range from regulation of cardiovascular function to participation in memory (Dawson *et al.*, 1992; Feldman *et al.*, 1993; Ignarro, 1989; Moncada *et al.*, 1991). In the immune system this diatomic radical is involved in various antipathogenic and tumoricidal responses (Hibbs, 1991; MacMicking *et al.*, 1997). Paradoxically, NO has also been implicated as a promoter of the severity of different diseases including cancer and stroke (Gross and Wolin, 1995; Wink *et al.*, 1998a). In fact, both protective and deleterious properties have been assigned to

NO even in the context of the same physiological event. Therefore, further mechanistic explanations are necessary to account for these contradictory effects.

Unlike most other biological mediators, the *in vivo* properties of NO are determined by its chemistry. Nitric oxide can undergo numerous reactions, and these often result in the formation of additional reactive nitrogen oxide species (RNOS). In an attempt to determine the pertinence of these diverse reactions to biological systems, we have developed the concept of the *chemical biology of nitric oxide* (Espey *et al.*, 2000; Wink and Mitchell, 1998; Wink *et al.*, 1996a,b, 1999). This scheme classifies the chemical reactions of NO into the two basic categories of direct and indirect effects (Fig. 1).

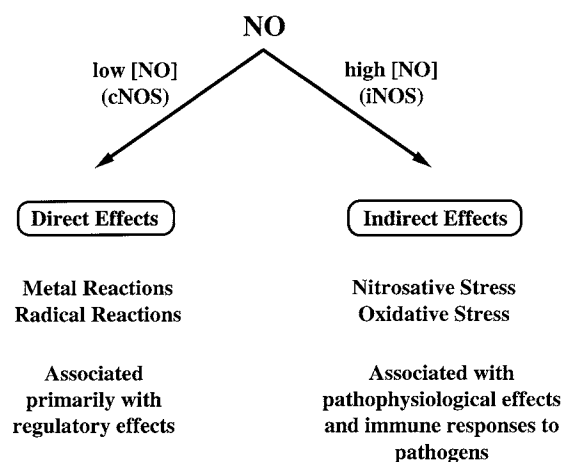

Figure 1 Chemical biology of nitric oxide.

Direct chemical reactions are those in which NO interacts directly with biological targets. The most common reactions of this type are between NO and heme-containing proteins. These reactions are generally rapid and are the genesis of the majority of the *in vivo* effects of NO. Conversely, indirect effects involve other RNOS, usually derived from the reactions between NO and O_2 or superoxide (O_2^-) rather than NO itself. Indirect effects require much higher concentrations of NO than direct reactions. Therefore, NO produced at low concentrations for short periods of time will primarily mediate direct effects, while indirect effects will occur in regions where higher local NO concentrations are sustained for prolonged time periods.

Direct and indirect effects correlate with the different isoforms of nitric oxide synthase (NOS) (Griffith and Stuehr, 1995; Nathan and Xie, 1994). A variety of cells such as endothelia (eNOS) and neurons (nNOS) express NOS constitutively. These isoforms can briefly generate submicromolar NO concentrations at the cellular level. Conversely, inducible NOS (iNOS) can produce NO for extended periods of time, with concentrations as high as $10\ \mu M$ in the vicinity of the cell (Lewis *et al.*, 1995). In general, the chemistry and the ultimate biological outcome of NO synthesis will be dictated by the isoform type. Additional consideration must be given to the proximity of the biological target to the NO source. Both direct and indirect effects would be expected to occur adjacent to cells such as activated macrophages, which produce high levels of NO, while more distant locations would primarily experience direct effects.

As the reactive intermediates responsible for the indirect effects of NO can also undergo a variety of reactions, indirect effects can be further subdivided into the categories of nitrosative and oxidative stress (Wink and Mitchell, 1998). Nitrosation mediated by RNOS appears to occur *in vivo* primarily through reaction with N_2O_3 , whereas oxidation is a consequence of peroxynitrite ($ONOO^-$) or nitroxyl (NO^-) ion formation (Wink *et al.*, 1999). Several studies indicate that nitrosative stress is orthogonal to oxidative stress (Wink and Mitchell, 1998; Wink *et al.*, 1997). It also appears that

biological effects such as cytotoxicity vary under nitrosative and oxidative stress (Wink and Mitchell, 1998). This suggests that there is a balance between these two types of stress and that a shift in this balance may determine the functional outcome in responses ranging from cell death to signal transduction. In this chapter, we explore the pertinent chemical reactions in the chemical biology of NO and discuss them in the context of oxidative and nitrosative stress.

Direct Effects

The primary criterion for the significance of direct reactions *in vivo* is reaction rate. The reactions in which NO combines with biological substrates at sufficiently rapid rates to be of consequence involve either metals or radicals (Fig. 2). Direct reactions between NO and thiols, for example, are far too slow to occur to any considerable extent.

The two major types of reactions between NO and biological metals are direct reactions with metal centers and redox reactions with metal dioxygen complexes or high valence metal-oxo complexes. These reactions are rapid, often nearing the diffusion controlled limit, and so are relevant under both physiological and pathophysiological conditions.

Reaction between NO and Metal Complexes

Nitric oxide reacts with a variety of metals to form nitrosyl complexes. The vast majority of these reactions *in vivo* are with metalloproteins containing iron. Although copper compounds will form nitrosyl complexes, the rates are too slow to be of major significance in the biology of NO (Cotton and Wilkinson, 1988). Other physiologically important transition metals such as zinc do not react with NO under biological conditions.

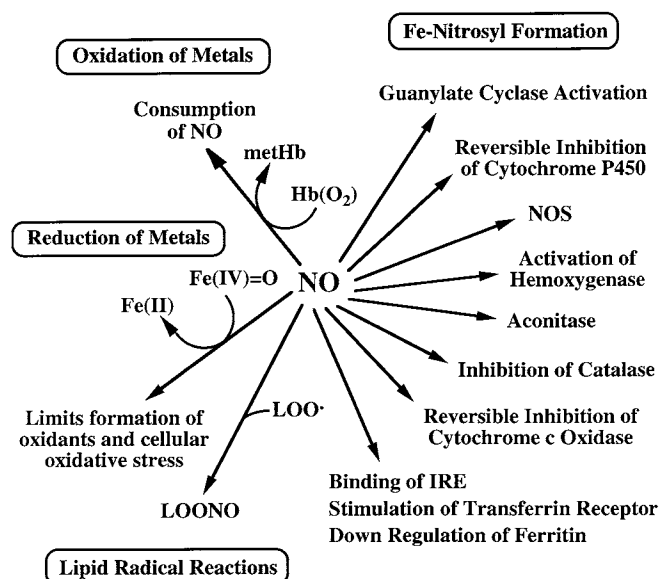

Figure 2 Direct effects of nitric oxide.

Nitrosylation of hemes is particularly facile and should be of primary consideration in any mechanism involving NO. Many basic regulatory functions involve reaction of NO with heme complexes such as guanylate cyclase, cytochrome P-450, NOS, and hemoglobin. The facility of these reactions is such that the NO source can be in another cell or even in different tissue than the target protein. On the contrary, reaction with the Fe-S cluster protein, aconitase, requires higher NO concentrations and thus a closer proximity to the NO source (Bouton *et al.*, 1996).

The most notable heme protein that forms an Fe-NO adduct *in vivo* is soluble guanylate cyclase (Murad, 1994). On NO binding, the position of the iron within the porphyrin ring is shifted such that the distal histidine is decoupled in favor of the five-coordinate nitrosyl complex (Stone and Marletta, 1994; Yu *et al.*, 1994). This alteration in protein configuration activates the enzyme at relatively low NO concentrations (EC_{50} of 100 nM; Forstermann and Ishii, 1996) and leads to conversion of guanosine triphosphate (GTP) to cyclic guanosine monophosphate (cGMP) in the GTPase domain. Production of cGMP has ramifications in a variety of tissues, but particularly in vascular smooth muscle where NO mediates vasodilation and has profound effects on platelet function as well as other intercellular interactions (Murad, 1994). Activation of guanylate cyclase by NO has also been suggested to prevent some apoptotic processes (Estevez *et al.*, 1998).

In contrast to guanylate cyclase, binding of NO to monooxygenases such as cytochrome P-450 results in potent competitive inhibition of O_2 binding to the heme site (Fig. 3) (Khatsenko *et al.*, 1993; Stadler *et al.*, 1994; Wink *et al.*,

1993a). Cytochrome P-450 enzymes require O_2 to facilitate oxidative chemistry via the production of iron-peroxo and high valence iron-oxo species. Inhibition of P-450 activity by NO has been postulated to regulate hormone metabolism such as testosterone synthesis (Adams *et al.*, 1992).

Nitric oxide-mediated inhibition of cytochrome P-450 has some important pathophysiological sequelae as well. The copious amounts of NO produced during chronic infection or septic shock can lead to inhibition of liver cytochrome P-450s (Stadler *et al.*, 1994; Wink *et al.*, 1993a) and subsequent repression of metabolism of clinically administered drugs (Khatsenko *et al.*, 1993). In contrast, binding of NO to the heme domain of cytochrome P-450 may serve as a protective mechanism against a variety of pathophysiological conditions by releasing free heme and activating hemeoxygenase in hepatocytes (Kim *et al.*, 1995a; Choi and Alam, 1996; Stocker, 1990). Thus, the interaction of NO with P-450s can have regulatory functions as well as deleterious or protective pathophysiological roles.

In the NOS protein, L-arginine is oxidized to L-citrulline and NO at the heme domain by a mechanism similar to substrate oxidation by cytochrome P-450 (Griffith and Stuehr, 1995). Nitric oxide can regulate its own synthesis through nitrosylation of this heme. Enzymatic oxidation is restricted by a negative feedback mechanism in which Fe-NO complex formation prevents O_2 binding at the active site (Abu-Soud *et al.*, 1995; Griscavage *et al.*, 1994, 1995; Hurshman and Marletta, 1995). Even under conditions of hyper intracellular calcium concentrations, this inhibition prevents production of significant amounts of RNOS from nNOS and eNOS. Compared to the constitutive NOS isozymes, the resultant Fe-NO complex in iNOS has a relative lower stability and thus a reduced susceptibility to inhibition by NO (Griscavage *et al.*, 1995). These data show that the predominant source of indirect effects *in vivo* may be from iNOS.

Competitive inhibition of NOS activity by NO can influence direct effects. In recent studies, NOS in lung alveoli was shown to produce NO in response to different concentrations of O_2 (Dweik *et al.*, 1998). Since NO and O_2 compete for the NOS heme binding site, the relative stability of the nitrosyl versus the dioxygen adduct determines the level of NO produced. Formation of the Fe-NO complex in NOS makes the K_m for O_2 binding linear in the physiological range suggesting that NOS may serve as both an O_2 sensor and a regulator of O_2 supply to tissue (Abu-Soud *et al.*, 1996). This mechanism may play a crucial role in regulating blood flow through different tissue in an O_2 tension-dependent manner.

Biological complexes containing metals other than iron are also affected by NO binding. As an example, nitrosylation of the aquo form of the vitamin B_{12} derivative cobalamin results in a diminished ability for this complex to serve as a cofactor for methionine synthase (Brouwer *et al.*, 1996). However, consideration of the consequences of nitrosylation must be extended from the effect on a particular compound to the impact on metabolism in general. For instance, an *in vivo* study showed that scavenging of NO by cobalamin reduced the loss in mean arterial blood pressure induced by

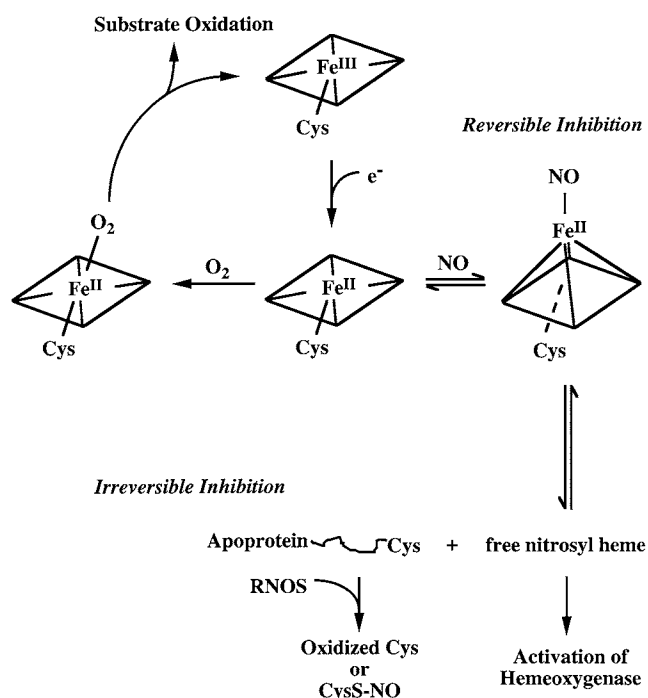

Figure 3 Mechanisms for NO-mediated inhibition of cytochrome P-450.

lipopolysaccharide (LPS) activated NOS (Greenberg *et al.*, 1995). Furthermore, the nitrosyl cobalamin complex can also perturb biological systems by nitrosating glutathione (GSH) or thiol-containing proteins, as discussed later (Brouwer *et al.*, 1996).

Interaction of NO with Metal–Oxygen and Metal–Oxo Complexes

The reactivity of NO with metals is not limited simply to covalent interactions. The rapid reaction between NO and oxyhemoglobin to produce methemoglobin and nitrate ($k = 5 \times 10^7 \text{ M}^{-1} \text{ s}^{-1}$; Eich *et al.*, 1996) is the primary endogenous mechanism by which NO diffusion and concentration are controlled (Doyle and Hoekstra, 1981; Feelisch, 1991; Lancaster, 1994).

Nitric oxide also reacts rapidly with metal–oxo and metal–peroxo species (discussed in Wink and Mitchell, 1998; Wink *et al.*, 1999). These highly reactive metal complexes are formed from oxidation by agents such as hydrogen peroxide (H_2O_2) and can result in cellular damage through mechanisms such as lipid peroxidation (Puppo and Halliwell, 1988).

The oxidative chemistry of these hypervalent metal complexes can be abated via reduction by NO to a normal valence (Gorbunov *et al.*, 1995; Kanner *et al.*, 1991; Wink *et al.*, 1994a).

Consumption of H_2O_2 by catalase is inhibited by cytokine stimulated hepatocytes and by synthetic NO donors (Kim *et al.*, 1995b; Wink *et al.*, 1996c). This reaction likely plays a role in the tumoricidal activity of stimulated macrophages (Farias-Eisner *et al.*, 1996). It is also of interest in this discussion, as catalase inhibition can occur through either metal nitrosyl formation or reaction with a metal–oxo species.

Nitric oxide binds to the catalase heme moiety to form a ferric nitrosyl complex with a rate constant of $3 \times 10^7 \text{ M}^{-1} \text{ s}^{-1}$ and a K_{dis} of $1 \times 10^5 \text{ M}^{-1}$ (Hoshino *et al.*, 1993). In analogy to inhibition of P-450 and NOS (Fig. 3; see above), the Fe–NO adduct prevents binding of H_2O_2 to the metal ion by occupying the coordination site. It is estimated that 10–15 μM NO inhibits H_2O_2 consumption by 80% by this mechanism (Farias-Eisner *et al.*, 1996). Since cells that express iNOS have reduced catalase activity, local NO concentrations may be this high for prolonged periods of time.

In the enzymatic mechanism (Fig. 4), H_2O_2 first reacts with catalase to form complex I ($\text{Fe}^{\text{V}}=\text{O}$) and H_2O in a manner similar to reaction (2). The enzyme is then regenerated by further reaction with H_2O_2 to produce O_2 and H_2O . However, NO can also rapidly react with complex I to form complex II and NO_2^- . Complex II then reacts with an additional

Figure 4 Interactions of nitric oxide with catalase.

NO to yield Fe^{3+} and NO_2^- . Thus, NO consumption retards H_2O_2 depletion with a K_i for NO of 0.18 μM (Brown, 1995a). This mechanism indicates that NO may inhibit H_2O_2 catabolism but, more importantly, that catalase may regulate NO concentration (Li *et al.*, 1992).

Reaction of NO with Radical Species

Lipid and carbon-centered radicals are formed as a result of both oxidative stress and normal metabolism. Nitric oxide can abate the effects these radicals have on biological systems. For instance, the catalytic turnover of ribonucleotide reductase produces a tyrosyl radical. Depletion of this radical by reaction with NO inhibits the enzyme (Kwon *et al.*, 1991; Lepoivre *et al.*, 1990, 1991, 1992). The resulting suppression of DNA synthesis is one of the deleterious (to the cell in question) functions of NO.

The interaction of NO with radicals can also have protective effects. Nitric oxide can react with oxyradicals formed during lipid peroxidation, which is an important component of the inflammatory process and cell death (Halliwell, 1991; Hogg *et al.*, 1993; Rubbo *et al.*, 1995). These oxyradicals convert lipids into a variety of lipid–oxy and lipid–peroxy adducts, which ultimately leads to cell membrane compromise through perpetuation of lipid oxidation (Fig. 5). Nitric oxide protects against reactive oxygen species (ROS) cytotoxicity by terminating lipid peroxidation (Gupta *et al.*, 1997; Padmaja and Huie, 1993; Wink *et al.*, 1994a, 1995).

In addition, lipid peroxidation induced by oxidants formed as a result of exposure to copper, xanthine oxidase, or azobisamidinopropane is terminated by NO (Hogg *et al.*, 1995; Rubbo *et al.*, 1995). Chain termination can prevent oxidation of low density lipoprotein in both endothelial (Struck *et al.*, 1995) and macrophage cells (Hogg *et al.*, 1995). Reduction of oxidized cholesterol levels is thought to impede initiation of atherosclerosis mediated by activated foamy macrophages.

Other processes in inflammation, such as production of leukotrienes from arachidonic acid, are also affected by NO.

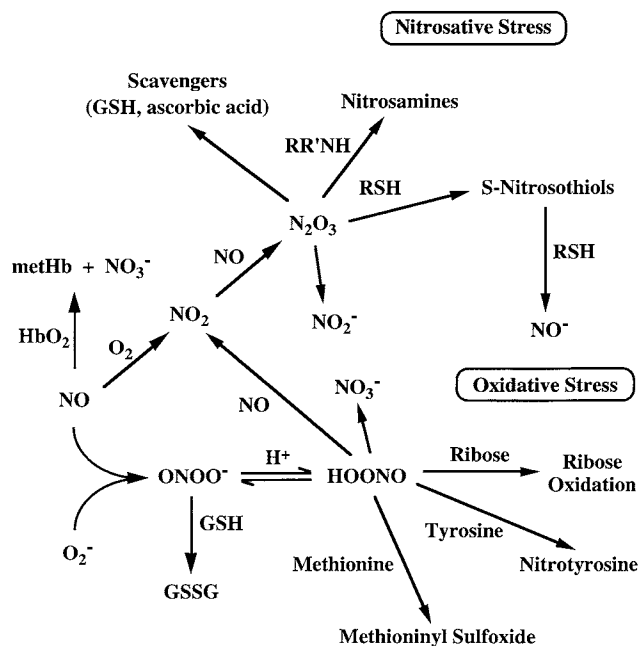

**Chain Termination****Chain Propagation****Figure 5** Chemistry of NO-mediated inhibition of lipid peroxidation.

Lipoxygenase, which mediates lipid oxidation, is inhibited by NO. At low concentrations, NO reacts with the lipid radicals directly, while at higher concentrations NO forms metal nitrosyl complexes that inhibit enzymatic activity. Therefore, arachidonic acid metabolism is influenced in a NO concentration-dependent manner.

Indirect Effects

The indirect effects of NO can be subdivided into the categories of nitrosation and oxidation. Nitrosation reactions primarily affect amines and thiols. Oxidation chemistry can result in the modification of a variety of macromolecules ranging from mild reducing agents such as catecholamines and metal centers to those with higher oxidation potentials such as DNA, proteins, and lipids. In biological systems, oxidation and nitrosation chemistry is a normal, constitutive component of cellular metabolism. However, these processes can also result in chemical intermediates that can stress the cell or produce toxic effects. In this instance the chemical reactions involved are referred to as nitrosative and oxidative stress. Under conditions of chemical stress, proteins and DNA can be irreversibly damaged. Thus, the indirect effects of NO are often associated with pathological conditions, and higher nitrogen oxides are thought to be the chemical species responsible for the etiology of numerous diseases.

The biological properties of these species, principally N_2O_3 , $ONOO^-$, NO^- , and NO_2 , are chemically driven much the same as NO itself (Fig. 6). For instance, N_2O_3 is a relatively mild oxidant that modifies substrates with potentials

**Figure 6** Chemistry of indirect effects.

of less than +0.7 V and thus does not affect biomolecules such as DNA. However, N_2O_3 will readily nitrosate nucleophiles and may be the principal nitrosating species *in vivo* (Wink *et al.*, 1996a). Conversely, the peroxyxynitrite and nitroxyl ions do not nitrosate substrates but can mediate oxidation of macromolecules (Miles *et al.*, 1996; Wink *et al.*, 1997; Wong *et al.*, 1998). A comparison of the resultant thiol products in the presence of various RNOS can illustrate this point. Aerobic NO solutions produce N_2O_3 and, when exposed to solutions of GSH, form the nitrosative product S-nitrosoglutathione (GSNO) nearly quantitatively (Wink *et al.*, 1994b). However, if GSH is exposed to $ONOO^-$, NO^- , or NO_2 , the major products are oxidized, not nitrosated, thiols (Doyle *et al.*, 1988; Pryor *et al.*, 1982; Radi *et al.*, 1991; Wong *et al.*, 1998).

To further complicate the issue, NO can react with $ONOO^-$, NO^- , and NO_2 (Pryor *et al.*, 1982; Wink *et al.*, 1997). For instance, the reaction between NO and $ONOO^-$ produces N_2O_3 (Beckman *et al.*, 1994; Koppenol *et al.*, 1992; Miles *et al.*, 1996).

This reaction facilitates thiol nitrosation at the expense of thiol oxidation and provides a means of balancing oxidative and nitrosative stress. In addition to these interactions with RNOS, NO can interact with ROS such as O_2^- to further abate oxidative chemistry. Therefore, it is not sufficient to consider a single reaction; one must contemplate many potential reactants and reactions. With this in mind, in the following sections we discuss the sources and conditions that might lead to nitrosative or oxidative stress, the chemical reactions that are responsible for both types of stress, and the likely biological targets.

Nitrosative Stress

The study of nitrosation chemistry dates back to the turn of the twentieth century (reviewed in Williams, 1988). In the mid 1970s nitrosation of amines derived from NO_2^- metabolism in the gastrointestinal tract became a concern as a potential source of carcinogens (Bartsch *et al.*, 1990). A decade later, the observations that nitrosamines and NO_2^- are produced as a result of infection or by activated leukocytes were critical links in the discovery of endogenous NO (Green *et al.*, 1981; Hibbs, 1991; Marletta, 1988; Stuehr and Marletta, 1985). S-Nitrosothiol (RSNO) formation has also been demonstrated to be physiologically relevant in processes ranging from cardiovascular function to cancer (Stamler, 1994; Wink *et al.*, 1998a).

Nitrosation is defined as the donation of a nitrosonium ion (NO^+) to a nucleophile, whereas nitrosylation is the formation of a nitrosyl adduct ($\cdot\text{NO}$) such as those between NO and metals as described earlier for direct effects. Both metals and RNOS mediate nitrosation, although to different extents. Transnitrosation between thiols may also affect protein function.

METAL-MEDIATED NITROSATION

Chemically, it is possible that metal-mediated nitrosation can occur. For example, iron containing compounds ranging from sodium nitroprusside to hemes can catalyze thiol and amine nitrosation. Generally, these compounds must be in the ferric state to transfer a nitrosonium ion such that substrates are reductively nitrosylated.

Cobalamin, which forms a stable $\text{Co}^{\text{III}}\text{-NO}$ complex under physiological conditions, has also been shown to nitrosate thiols (Brouwer *et al.*, 1996).

Under anaerobic conditions, ferrous nitrosyl hemes are quite stable. However, the corresponding ferric complexes require high NO concentrations for stability, as NO easily disassociates from the ferric ion. Additionally, heme- and iron-mediated nitrosation of amines requires an atmosphere of NO for days (Wade and Castro, 1990). These are conditions unlikely to be encountered *in vivo*. Metal-induced nitrosation also does not result in deamination of DNA or nitrosation of lysine groups.

Physiological transport of NO and the formation of S-nitrosothiols may occur through nonheme iron sulfur nitrosyl complexes such as those observed in activated macrophages. Under high fluxes of NO, formation of these complexes has been indicated by electron paramagnetic resonance (EPR) spectroscopy (Lancaster and Hibbs, 1990). Ferritin, aconitase, and even metallothionein are responsible for the EPR signal observed in activated macrophages. These observations imply that S-nitrosothiol formation may occur via these nonheme nitrosyl complexes.

Studies have been conducted to mimic the chemistry of these complexes. Nitrosation of thiols can be catalyzed by ferrous iron under anaerobic conditions. As this

chemistry is readily reversible, it is not likely to account for inactivation of enzymes in cells exposed to high NO concentrations but may produce a small amount of S-nitrosothiol. However, studies using different NO donors showed that enzymes such as DNA-repair enzymes are not inhibited by GSNO (Laval and Wink, 1994; Wink and Laval, 1994), and this chemistry [Eq. (7)] **cannot** be a mechanism for nitrosative stress. As a result, metal-mediated nitrosation has a minor role at best *in vivo*.

RNOS-MEDIATED NITROSATION

Generally, nitrosation *in vivo*, particularly of amines, is a result of RNOS formation. As described below, there are three potential sources for these RNOS (Fig. 7): the autoxidation of NO, the dehydration of acidic NO_2^- , and the NO/ O_2^- reaction under an excess of NO. With the exception of the gastric regions ($\text{pH} < 1.5$) where NO^+ can be formed from acidic NO_2^- , the primary nitrosating intermediates are isomers of N_2O_3 .

The chemical reaction most noted for the formation of N_2O_3 is the autoxidation, or reaction with O_2 , of NO. This reaction has been studied for decades due to its importance in nitrogen oxide chemistry in the atmosphere (Schwartz and White, 1983). In aqueous, hydrophobic, and gas phases, the autoxidation of NO has a third order rate equation with a second order dependence on NO.

Due to the instability of NO in the presence of O_2 as well as its role in the formation of toxic chemical species such as NO_2 and N_2O_3 , it was difficult to envision why nature would choose NO as a physiological mediator. However, the lifetime of NO, which is inversely proportional to its concentration, is dictated by the second order dependence of the autoxidation reaction [Eq. (8)] (Ford *et al.*, 1993; Wink *et al.*, 1993b). Therefore, as NO diffuses away from the cellular

Figure 7 Nitrosative stress.

source and is thereby diluted, its lifetime increases sufficiently to allow it to react with other biological targets such as guanylate cyclase. It is only in local regions of high NO output where intermediates associated with NO autoxidation will be formed to a significant extent *in vivo*.

The rate constants for the autoxidation of NO in hydrophobic and aqueous solutions are similar ($k \approx 8 \times 10^6 M^{-2} s^{-1}$; Ford *et al.*, 1993), whereas the concentrations of NO and O₂ are 10–50 times higher in lipid membranes than in aqueous solution (Denicola *et al.*, 1996). Consequently, the rate of autoxidation is dependent on the solubility of both NO and O₂ in a particular medium. Exposure to a NO flux from either a chemical donor or an *in vivo* source results in NO levels at least 10 times higher in membranes than in the surrounding medium and a corresponding elevation in the rate of autoxidation. In micelles this rate was demonstrated to increase 1500 times as compared to that in aqueous solution (Liu *et al.*, 1998). For this reason, nitrosation reactions mediated via the autoxidation reaction are likely to predominate in the membrane where proteins that are functionally and structurally dependent on thiols or amines would be most affected by nitrosative stress. However, thiol nitrosation is also an important pathway in membrane-associated protein chemistry.

PEPTIDE-MEDIATED NITROSATION

Small thiol peptides such as glutathione and cysteine can also be affected by nitrosative stress. In turn, these RSNO species can influence cellular metabolism and cardiovascular function by transnitrosating (transfer of NO⁺) other reduced thiols (Stamler, 1994). This has been proposed as a mechanism by which NO can be transported through biological systems. The interaction of S-nitrosothiol peptides and reduced thiols can also result in reductive elimination of NO⁻ (Arnette and Stamler, 1995). In addition, GSNO can react with various iron (Vanin, 1995) and copper complexes (Goren *et al.*, 1996; Williams, 1996) and with O₂⁻ (Aleryani *et al.*, 1998; Jourdeuil *et al.*, 1998; Trujillo *et al.*, 1998).

Low-molecular-weight thiols for the most part are less stable than proteins. For instance, CysNO in biological solutions has a shorter half-life than GSNO, which in turn has a shorter lifetime than S-nitrosothiol proteins (Feelisch and Stamler, 1996). Therefore, CysNO will typically transfer NO⁺ to higher molecular weight thiols more quickly than GSNO. Zinc finger proteins are exceptions, as they do not react with RSNOs (Wink and Laval, 1994). However, as transnitrosation is often an equilibrium reaction in which the products are thermodynamically controlled, proteins such as alkyltransferases are not irreversibly inhibited by GSNO and CysNO (Laval and Wink, 1994). Inactivation of these proteins requires RNOS mediated nitrosation.

MECHANISM OF N₂O₃ FORMATION

The above sections demonstrate that nitrosative stress is primarily driven by N₂O₃. The mechanisms by which N₂O₃ is formed are crucial to the chemistry of nitrosative stress. The autoxidation of NO in either the gas phase or in hydro-

phobic solvents initially produces NO₂ [Eq. (8)]. Further reaction between NO and NO₂ results in an equilibrium with N₂O₃.

In aqueous solution, competition reactions showed that NO₂ could not be trapped during the autoxidation of NO (Wink and Ford, 1995; Wink *et al.*, 1993b). These data suggest that dimerization to N₂O₄ occurs before NO₂ can escape the solvent cage. Under these conditions, formation of N₂O₃ takes place by Eq. (10) rather than Eq. (9).

Subsequently, N₂O₃ rapidly converts to nitrite in the absence of substrate.

Whether autoxidation takes place in hydrophobic/gas phase or in aqueous media affects the subsequent RNOS chemistry. For example, exposure of tyrosine to RNOS synthesized in the gas phase or from acidified nitrite solutions resulted exclusively in nitrotyrosine formation (Wink *et al.*, 1994b). However, this product was not observed as a result of the autoxidation reaction in H₂O. These findings suggest that nitrotyrosine formation by NO autoxidation is more likely to occur in hydrophobic environments such as membranes than in the cytosol.

Since N₂O₃ is hydrolyzed to NO₂⁻ with a half-life of 1 ms in aqueous media, only substrates that are present in high enough concentrations and have sufficient affinity will react with N₂O₃ (Wink *et al.*, 1996d). Thiol-containing peptides have an affinity for N₂O₃ that is 1000 times greater than any other amino acid at neutral pH. The primary products of the NO/O₂ reaction in aqueous solutions or biological media will likely then be S-nitrosothiols and nitrite (Wink *et al.*, 1994b, 1996d).

Oxidative Stress

Oxidation, or the removal of electrons from a substrate, occurs as part of normal metabolism. However, there is a significant difference between this cellular redox chemistry and that associated with oxidative stress. Under conditions of oxidative stress, powerful oxidizing agents abnormally modify biomolecules affecting their function and severely impacting the health status of cells or tissue. For example, oxidation of DNA can lead to strand breaks (Halliwell and Gutteridge, 1984). Unabated oxidation of lipids and proteins is associated with the onset of numerous pathophysiological conditions, and chronic oxidative stress is involved in the etiology of many disease states.

RNOS-mediated oxidative stress is induced primarily by NO₂, ONOO⁻, and NO⁻. The autoxidation of NO and the dehydration of acidic NO₂⁻ can form NO₂, while both NO₂ and ONOO⁻ can be produced by the reaction between NO

and O_2^- . Interestingly, these are the same pathways that can lead to nitrosative stress. This unequivocally demonstrates that a dynamic equilibrium exists between oxidative and nitrosative reactions during periods of cellular stress.

NO₂-MEDIATED OXIDATIVE STRESS

The reactivity of NO₂ illustrates that this balance is controlled by the local NO concentration. The autoxidation of NO [Eq. (8)] is one mechanism by which NO₂ is produced. However as discussed earlier, this reaction occurs to a significant extent *in vivo* only in regions of high NO output. Under these conditions, NO₂, formed by any mechanism, will react with excess NO to yield N₂O₃ [Eq. (9)], thus stimulating nitrosative rather than oxidative stress. Conversely, the acidification of NO₂⁻ does not require free NO (Williams, 1988).

At sufficiently low NO concentrations, the equilibrium in Eq. (9) will favor N₂O₃ disproportionation into NO₂ and NO. Although NO₂ does not appear to alter DNA (Routledge *et al.*, 1994a,b), this reaction can induce lipid peroxidation (Pryor, 1982).

Excess NO [Eq. (5)] or O_2^- [Eq. (16)] can react with ONOO⁻ to form NO₂ (Beckman *et al.*, 1994; Koppenol *et al.*, 1992; Miles *et al.*, 1996).

This imparts a further balance between oxidative and nitrosative stress. However, the oxidative chemistry mediated by NO₂ *in vivo* is probably limited to regions of low pH or high (relative to NO) O_2^- concentrations.

NO/ O_2^- CHEMISTRY

The reaction between NO and O_2^- produces the powerful oxidant, ONOO⁻ (Huie and Padmaja, 1993; Pryor and Squadrito, 1995).

The observation that superoxide dismutase (SOD) enhanced the effect of endothelial-derived relaxing factor (EDRF) (Furchgott and Zawadzki, 1980) was followed by a large literature on its potential importance in biological systems (Beckman *et al.*, 1990). Although the rate constant for ONOO⁻ formation approaches diffusion control, the relative pseudo first order rate constant is of equal importance in determining whether a reaction occurs *in vivo*. In other words, the impact a particular reaction will have *in vivo* is governed by the concentration of the reactants as much as by the rate constant (for a summary of evaluating RNOS, see Wink *et al.*, 1996d).

The estimated cellular concentrations of O_2^- and NO under normal conditions are 1 pM and 0.1–1 μM, respectively (Tyler, 1975). Thus, the location and amount of ONOO⁻ formation from reaction between these two radicals are

likely to be controlled by O_2^- production. Since O_2^- reacts with SOD and NO with similar rate constants, ONOO⁻ formation will also be dependent on the competing reaction of O_2^- with SOD. The intracellular concentration of SOD is thought to be between 4 and 10 μM, while the mitochondrial enzyme, MnSOD, content is probably as high as 50 μM (Nakano *et al.*, 1990). Therefore, in order for 10% of the available O_2^- to be converted to ONOO⁻, the NO concentration would have to be 0.4–5 μM. In addition, other reaction partners of O_2^- such as aconitase ($3 \times 10^7 \text{ M}^{-1} \text{ s}^{-1}$) and ferricytochrome *c* ($5 \times 10^6 \text{ M}^{-1} \text{ s}^{-1}$) could also abate ONOO⁻ production, although to a lesser extent. Therefore, the reaction of O_2^- with NO will be constrained to specific sites (Fig. 8).

In neutral solution, ONOO⁻ has been shown to be a potent modifier of biological compounds through oxidation of thiols, initiation of lipid peroxidation, nitration of tyrosine, cleavage of DNA, and nitration or oxidation of guanosine and methionine. The modifying species is an excited state of peroxynitrous acid (HOONO*) (Koppenol *et al.*, 1992). In the absence of adequate substrate, HOONO* simply rearranges to NO₃⁻ (Fig. 9). This isomerization can be considered as a detoxification pathway. However, in high enough concentrations, substrates such as tyrosine can react with HOONO* (1 mM to yield 50% nitrotyrosine).

The direct interactions between metals and ONOO⁻ can catalyze substrate modifications. For example, the metals in SOD and FeEDTA enhance nitration reactions (Beckman *et al.*, 1992). Heme containing enzymes such as myeloperoxidase ($k = 6 \times 10^6 \text{ M}^{-1} \text{ s}^{-1}$) and lactoperoxidase ($k = 3.3 \times 10^5 \text{ M}^{-1} \text{ s}^{-1}$) also react with ONOO⁻ (Floris *et al.*, 1993) such that complex II is formed (Fig. 4). In contrast, horseradish peroxidase ($k = 3.2 \times 10^6 \text{ M}^{-1} \text{ s}^{-1}$) is converted to complex I by ONOO⁻. Floris *et al.* proposed an interesting mechanism by which complex I is initially formed and then

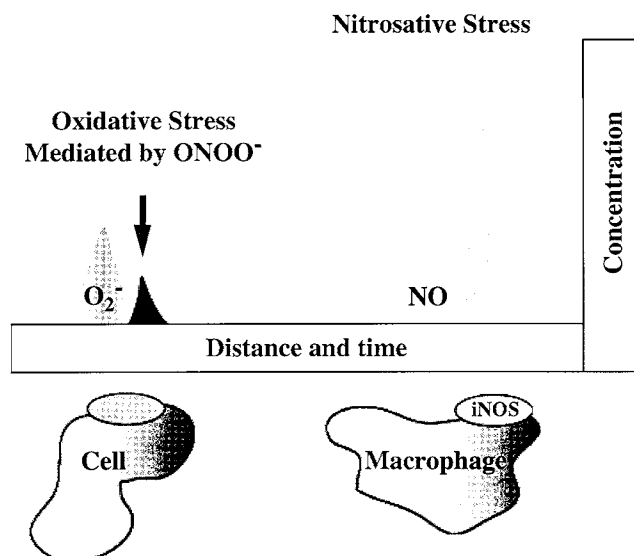

Figure 8 Implications of distance and time with respect to nitrosative and oxidative stress in the NO/ O_2^- reaction.

Figure 9 Chemistry of formation and reactivity of peroxynitrite.

rapidly oxidizes NO_2^- to NO_2 . In the presence of NO, a number of nitrosation reactions would subsequently be facilitated via N_2O_3 [Eq. (9)]

As ONOO^- reacts with excess NO and O_2^- [Eqs. (5) and (16)], the effects of variance in the reactant fluxes on the balance between nitrosative and oxidative chemistry were examined using NO donors and xanthine oxidase (XO) (Jourdeuil *et al.*, 1999; Miles *et al.*, 1996; Wink *et al.*, 1997). Xanthine oxidase is considered to be a model for oxidative stress and generates the ROS, O_2^- and H_2O_2 . The oxidation of hypoxanthine and the production of H_2O_2 from XO were unaffected by the presence of the NO releasing agent DEA/NO [$(\text{C}_2\text{H}_5)_2\text{N}[\text{N}(\text{O})\text{NO}]^-\text{Na}^+$] (Wink *et al.*, 1996c). However, the amount of O_2^- formed was dramatically reduced due to reaction with NO to form ONOO^- , which then isomerizes to NO_3^- (Fig. 9) (Clancy *et al.*, 1992; Miles *et al.*, 1995; Rubbo *et al.*, 1994; Wink *et al.*, 1993c). Addition of dihydrodhamine (DHR) to the reaction mixture resulted in an increase in substrate oxidation to rhodamine (Miles *et al.*, 1996). The hypothesis that ONOO^- is a RNOS generated from the interaction of NO with O_2^- generated from XO is further supported by these data (Kooy *et al.*, 1994; Jourdeuil *et al.*, 1999).

A crucial finding of this study is that maximal oxidation was only achieved at a 1:1 ratio of NO to O_2^- . When either radical was in excess, DHR oxidation was quenched due to conversion of ONOO^- to NO_2 [Eqs. (5) and (16)] (Beckman *et al.*, 1994; Koppenol *et al.*, 1992; Miles *et al.*, 1996). Under conditions of excess NO, NO_2 is converted to the nitrosating species, N_2O_3 [Eq. (9)], illustrating an additional mechanism

by which oxidative stress can be transformed to nitrosative stress by the action of NO (Fig. 8). This places further restrictions on the chemistry mediated directly by ONOO^- . We emphasize that the predominant factor is relative concentrations of the reactants involved in nitrogen oxide chemistry.

NO^- -Mediated Oxidative Stress

The nitroxyl anion is a species with emerging importance in the understanding of nitrogen oxide biology. Nitroxyl can be formed as a result of several different processes. A primary source of NO^- is the nucleophilic attack of reduced thiols by RNOS to form RSNO , which can subsequently form NO^- and disulfide.

Decomposition of dithiothreitol-S-nitrosothiol to oxidized thiol can release NO^- by a similar mechanism (Arnette and Stamler, 1995; Wink and Feelisch, 1996).

Nitroxyl has also been suggested to be formed from the decomposition of iron dinitrosyl complexes similar to those observed in tumor cells exposed to activated macrophages (Bonner and Pearsall, 1982). Last, NO^- may be derived from NOS (Hobbs *et al.*, 1994; Schmidt *et al.*, 1996). The mechanism may entail oxidation of hydroxyarginine, which is an intermediate in NOS activity (Pufahl *et al.*, 1995).

The synthesis of several substances that release NO^- has provided a method to study the effects of NO^- in biology (Feelisch and Stamler, 1996). Angeli's salt (AS; $\text{Na}_2\text{N}_2\text{O}_3$) releases NO^- and NO_2^- at neutral pH. Nitroxyl is isoelectric to O_2 and most frequently exists in either the triplet ground state or a singlet excited state. As the reactivity of a compound is in part controlled by its state, defining the state of AS is fundamental to understanding its chemistry. Nitroxyl is released from AS in the singlet state (Bonner and Stedman, 1996) and reacts with substrates, generally other singlets, more quickly than intersystem crossing (or state changes) to the ground state occurs.

In biological systems, NO^- can react by either an oxygen-independent or an oxygen-dependent pathway. Our preliminary results indicate that amines (e.g., hydroxylamine) and thiols rapidly react directly with NO^- . In addition, NO^- can react directly with NO, NADPH, and metalloproteins (e.g., SOD, myoglobin, and catalase) (Murphy and Sies, 1991; Wink *et al.*, 1998b; Miranda and Wink, 1999, personal observations). The NO^- reactions that require O_2 include hydroxylation and oxidation (e.g., methionine modification) and may figure prominently in NO^- -mediated cytotoxicity (Wink *et al.*, 1998b).

The toxicity of AS toward Chinese hamster V79 fibroblasts is two orders of magnitude greater than that of NO released from SIN-1 (3-morpholininosynonimine) and the NONOate, DEA/NO, and comparable to that of H_2O_2 and

alkylhydroperoxide. Hypoxia abates NO^- toxicity, which demonstrates a requirement for reaction between NO^- and O_2 . The lack of effect of metal chelators indicates that ROS produced via Fenton type reactions are not involved. A unique consequence of NO^- -mediated cytotoxicity is the formation of DNA double strand breaks. This characteristic is not observed with either H_2O_2 or ONOO^- .

Although the reaction between NO^- and O_2 might be expected to give the same product as the reaction between NO and O_2^- , a preliminary analysis using several oxidative probes showed that ONOO^- is not involved (Wink *et al.*, 1998b). Similar selectivity for two-electron oxidation of DHR to the fluorescent compound rhodamine was observed for NO^- from AS and for ONOO^- . However, the oxidative yield from AS was twice that for ONOO^- . Oxidation of DHR by AS was not quenched by azide, which indicates that N_2O_3 is not a component of NO^- chemistry. Peroxynitrite is very effective at nitrating and oxidizing (by one electron) hydroxyphenylacetic acid (HPA) but is a poor hydroxylating agent for benzoic acid. In contrast, AS is an efficient hydroxylating agent but fails to oxidize or nitrate HPA. Therefore, NO^- and O_2 produce an intermediate that is distinct from ONOO^- .

Characterization of this intermediate was undertaken. The stoichiometry of the NO^-/O_2 reaction was determined to be one to one (Wink *et al.*, 1998b). Singlet NO^- from AS decomposition in aqueous solution is proposed to react with H_2O (singlet ground state) to form an equilibrium with the hydrated species, H_2ONHO . This hydrated HNO adduct then could react with O_2 to form $(\text{OH})_2\text{NOO}^-$ (Fig. 10). The intermediate decomposes to form NO_3^- and NO_2^- approximately equally. In the presence of HEPES, up to 25% H_2O_2 is also generated (Miranda and Wink, unpublished data, 1999). The intermediate, $(\text{OH})_2\text{NOO}^-$, may be the species responsible for the oxidative chemistry and the cytotoxicity under aerobic conditions in cells. The inability of metal chelators to abate toxicity eliminates H_2O_2 as the toxic agent.

Mixed Direct and Indirect Effects

When elucidating mechanisms under conditions that produce indirect effects, it is important to consider direct effects as well. One may envision direct effects occurring within the NO -generating cell, as well as within neighboring or distant cells, concurrently with indirect effects depending on the redox environment.

NO Inhibition of Mitochondrial Respiration

A primary cellular target for the cytotoxic action of NO is the mitochondrion (Hibbs *et al.*, 1987; Lancaster and Hibbs, 1990; Moncada *et al.*, 1991). Dinitrosyl adducts of aconitase were observed in activated macrophages by EPR (Lancaster and Hibbs, 1990), showing that iNOS catalyzed chemistry results in mitochondrial inhibition within the source cells and potentially causes cytostasis or cytotoxicity

Figure 10 Possible mechanism for the oxidative chemistry of nitroxyl in the presence of oxygen.

in target cells. However, the effects of NO can also be regulatory rather than deleterious.

Nitric oxide can repress oxidative phosphorylation in a reversible manner through regulation of intracellular calcium levels (Laffranchi *et al.*, 1995; Schweizer and Richter, 1994). Additionally, nitrosylation of cytochrome *c* oxidase reversibly inhibits respiration (Brown *et al.*, 1995; Brown, 1995b; Cassina and Radi, 1996; Cleeter *et al.*, 1994; Poderoso *et al.*, 1996; Lizasoain *et al.*, 1996; Rousseau *et al.*, 1988). The enzyme reverts to the active state when the bound NO is reduced to nitrogenous products by electrons from the respiratory chain (Borutaite and Brown, 1996; Clarkson *et al.*, 1995). Under aerobic conditions, O_2^- is formed when the electrons are diverted from the Fe-NO adduct to the O_2 binding site (Fig. 11) (Poderoso *et al.*, 1996). This O_2^- -dependent partitioning between the reduction of NO and O_2 results in respiration modulation by low levels of NO . The interesting possibility of intraorganelle regulation of tissue O_2 levels is raised by demonstration of an eNOS-like isoform in mitochondria (Bates *et al.*, 1996).

Similar to the mechanism described earlier for cytochrome P-450 (Fig. 3), inhibition of mitochondrial respiration appears to have a reversible component mediated by direct effects and an irreversible component mediated by indirect effects. Deciphering which oxidative and nitrosative

Figure 11 Nitric oxide and mitochondrial function.

mediators are involved in the pathogenic inhibition of mitochondrial functions is key to understanding disease mechanisms. RNOS may play a role in irreversible inhibition of complex I (NADH:ubiquinone oxidoreductase) and complex II (succinate:ubiquinone oxidoreductase) (Cassina and Radi, 1996) under inflammatory conditions in which cells can experience prolonged exposure to high levels of NO. As NO concentrations and time of exposure increase, there are corresponding increases in RNOS formed in the mitochondria (Fig. 8). Under aerobic conditions, O₂⁻ is a product of respiration and can react with NO to form ONOO⁻. A significant role for ONOO⁻ in mitochondria has been suggested. Both GSH and glucose prevented inhibition of mitochondrial respiration by ONOO⁻, which suggests that this species is unlikely to directly inhibit respiration in cells unless it is formed within the mitochondria (Lizasoain *et al.*, 1996). However, the high concentration of mitochondrial MnSOD limits ONOO⁻ formation. The amount of NO required to form ONOO⁻ results in higher NO fluxes than O₂⁻ fluxes, favoring the conversion of ONOO⁻ to N₂O₃ [Eqs. (5) and (9)]. These conditions indicate that the oxidative chemistry mediated by ONOO⁻ probably does not play a significant role in mitochondrial function or dysfunction. Rather other RNOS such as NO₂ and N₂O₃ are likely responsible for irreversible inhibition of cellular respiration, and nitrosative, not oxidative, chemistry would be the predominant indirect effect in mitochondria under high NO fluxes.

The body may have several protective mechanisms to limit the indirect effects of RNOS on mitochondria. Inhibition of respiration was not observed in cells isolated from sites of experimentally induced inflammation *in vivo* (Fisch *et al.*, 1996; Stadler *et al.*, 1991). This may suggest that oxyhemoglobin and diffusion of NO away from NOS containing cells play important roles in the extent of mitochondrial inhibition where RNOS formation is limited and reversible inhibition is only transient.

Metal Homeostatics

Nitric oxide can regulate intracellular iron status under either physiological or pathophysiological conditions (see reviews in Drapier and Bouton, 1996; Hentze and Kuhn, 1996). Ferrochelatase is the enzyme that incorporates iron into the porphyrin center. Nitric oxide can substantially inhibit this process by direct interaction with the Fe-S complex while increasing the activity of the heme catabolic enzyme, heme oxygenase (Kim *et al.*, 1995a). These actions reduce the overall heme availability including that for the heme domain of NOS, which may serve as a negative feedback mechanism for NO formation.

Nitric oxide interacts with iron responsive-binding proteins (IRB) to regulate the uptake and storage of cellular iron. As their names imply, IRBs regulate the translation of proteins containing iron responsive element (IRE) motifs in their mRNA such as transferrin receptor and ferritin (Drapier and Bouton, 1996; Hentze and Kuhn, 1996; Klausner *et al.*, 1993). Interestingly, the mitochondrial enzyme aconitase acts as an IRB in the cytoplasm. The iron sulfur cluster within this IRB has two forms, apoprotein (Fe₃S₄) and holoprotein (Fe₄S₄), with the fourth iron in the apical position. The loss of iron at this site signals an overall cellular requirement to increase iron levels. Binding of IRB apoproteins to their respective IREs results in upregulation of transferrin receptor and downregulation of ferritin production (Klausner *et al.*, 1993). Conversely, the intact Fe-S cluster in IRBs leads to a reduction of iron uptake.

Nitrosylation of the apical iron results in Fe-NO expulsion to give the Fe₃S₄ cluster. This direct effect leads to inhibition of aconitase activity and to IRB binding to the IRE (Fig. 12). Although ONOO⁻ and O₂⁻ also inhibit aconitase activity, they decrease the ability of IRB to bind to the IRE (Castro *et al.*, 1994; Hausladen and Fridovich, 1994). Oxidative inactivation of aconitase by either ONOO⁻ or O₂⁻ may limit iron availability as a *protective* mechanism against Haber-Weiss chemistry. Iron is released from ferritin by an O₂-mediated mechanism involving NADPH oxidase. Through direct inhibition of NADPH oxidase assembly (Clancy *et al.*, 1992), NO can decrease the availability of ferrous ion. In addition, the indirect effect of O₂⁻ scavenging by NO inhibits the reduction of ferritin bound iron. These examples illustrate the complex checks and balances that have evolved in the regulation of basal metabolism and in protection against oxidative stress by NO.

Conclusion

The chemical biology of NO outlined in this chapter is meant to provide a guide for investigation of the cellular and molecular aspects of NO. The importance of concentration and timing with ROS cannot be overstated. Direct effects predominate in normal physiology, however, indirect effects can govern the characteristics of NO during pathology. With stoichiometric, temporal, and spatial considerations, the po-

tential reactions of NO can be placed in proper context for biological systems.

PEROXYNITRITE ANION (ONOO^-) IS FORMED *IN VIVO* AS A RESULT OF THE DIFFUSION-CONTROLLED REACTION BETWEEN NITRIC OXIDE ($\cdot\text{NO}$) AND SUPEROXIDE ANION ($\text{O}_2^{\cdot-}$) RADICALS. PEROXYNITRITE ANION AND ITS CONJUGATED ACID, PEROXYNITROUS ACID (ONOOH , $\text{p}K_a = 6.8$), ARE STRONG OXIDANT SPECIES THAT CAUSE MOLECULAR DAMAGE IN A VARIETY OF PATHOPHYSIOLOGICAL CONDITIONS. PEROXYNITRITE REACTS FAST ($k \approx 10^3\text{--}10^6\text{ M}^{-1}\text{ s}^{-1}$) WITH A NUMBER OF BIOLOGICAL TARGETS, INCLUDING THIOLS, METALLOPROTEINS, AND CARBON DIOXIDE, OR MORE SLOWLY DECOMPOSES TO HYDROXYL ($\cdot\text{OH}$) AND NITROGEN DIOXIDE ($\cdot\text{NO}_2$) RADICALS BY PROTON-CATALYZED HOMOLYSIS ($k = 0.9\text{ s}^{-1}$ AT pH 7.4 AND 37°C). CARBON DIOXIDE ACCOUNTS FOR A SIGNIFICANT FRACTION OF PEROXYNITRITE CONSUMPTION AND LEADS TO THE SECONDARY FORMATION OF CARBONATE ($\text{CO}_3^{\cdot-}$) AND NITROGEN DIOXIDE ($\cdot\text{NO}_2$) RADICALS. AT THE MOLECULAR LEVEL, THE PREDOMINANT OUTCOME OF PEROXYNITRITE REACTIONS *IN VIVO* IS ONE- OR TWO-ELECTRON OXIDATIONS AND NITRATIONS. PROTEIN TYROSINE NITRATION REPRESENTS A KEY FOOTPRINT OF THE BIOLOGICAL FORMATION AND REACTIONS OF PEROXYNITRITE, AND CAN ALSO DIRECTLY CONTRIBUTE TO PEROXYNITRITE-MEDIATED TOXICITY. WHEREAS TYROSINE NITRATION BY PEROXYNITRITE IS A RELATIVELY LOW-YIELD PROCESS ($\sim 6\%$), YIELDS ARE SIGNIFICANTLY ENHANCED BY TRANSITION METALS AND CARBON DIOXIDE. PEROXYNITRITE CAN DIFFUSE THROUGH TISSUE COMPARTMENTS, BEING ABLE TO CROSS BIOMEMBRANES BY BOTH PASSIVE DIFFUSION AND ANION CHANNELS. THUS, ALTHOUGH THE BIOLOGICAL HALF-LIFE OF PEROXYNITRITE IS SHORT ($< 20\text{ ms}$), IT IS SUFFICIENT FOR PEROXYNITRITE TO DIFFUSE A COUPLE OF CELL DIAMETERS AND CAUSE BIOLOGICAL EFFECTS DISTANT FROM ITS SITE OF PRODUCTION. CELLULAR DYSFUNCTION BY PEROXYNITRITE RELIES ON A COMBINATION OF MECHANISMS, MOST NOTABLY MITOCHONDRIAL DAMAGE, WHICH MAY CONTRIBUTE TO THE INITIATION OF PEROXYNITRITE-MEDIATED APOPTOSIS. AT THE EXTRACELLULAR LEVEL, PEROXYNITRITE IS IMPLICATED IN THE ATHEROGENIC PROCESS VIA LOW-DENSITY LIPOPROTEIN OXIDATION OF CRITICAL AMINO ACID RESIDUES IN APO-B-100 AND BY INITIATING LIPID OXIDATION. PHARMACOLOGICAL DEVELOPMENT OF PEROXYNITRITE SCAVENGERS IS BASED ON OUR CURRENT KNOWLEDGE OF ITS REACTION CHEMISTRY AND BIOLOGY. HEREIN, WE PROVIDE A COMPREHENSIVE OVERVIEW OF THE PHYSICAL AND BIOLOGICAL CHEMISTRY OF PEROXYNITRITE. THE AIM IS TO PROVIDE A FOUNDATION TO RATIONALIZE THE BIOLOGICAL FATE AND ACTIONS OF PEROXYNITRITE AND THE STRATEGIES FOR PREVENTING PEROXYNITRITE-DEPENDENT BIOLOGICAL DAMAGE AND PATHOLOGY.

Introduction

Excess production of the free radicals nitric oxide ($\cdot\text{NO}$) superoxide (O_2^-) is related to cell and tissue pathology (Beckman and Koppenol, 1996; Freeman and Crapo, 1982; White *et al.*, 1994). Unraveling the mechanisms by which these moderately reactive radicals disrupt biomolecular structure and function has been challenging due to both their transient nature and the potential multiplicity of cellular and extracellular target molecules. Substantial progress was made when a hypothesis was elaborated in the early 1990s, proposing that the pathways of $\cdot\text{NO}$ and O_2^- -dependent molecular damage can merge into a common route involving the formation of peroxynitrite anion (ONOO^-) (Beckman *et al.*, 1990; Radi *et al.*, 1991a,b).

After the identification of $\cdot\text{NO}$ as a cellular messenger, the interaction of $\cdot\text{NO}$ with O_2^- became evident (Ignarro *et al.*, 1987; Palmer *et al.*, 1987). Early experiments showed that superoxide dismutase (SOD) prolonged the half-life and biological effects of the endothelium-derived relaxing factor (EDRF) (Gryglewski *et al.*, 1986; Rubanyi and Vanhoutte, 1986). Furthermore, a number of compounds described as inhibitors of EDRF were shown to act by generating O_2^- in solution as a result of their redox properties, and SOD attenuated their actions on EDRF (Moncada *et al.*, 1986). Initially thought to represent a "scavenging" mechanism for $\cdot\text{NO}$ leading to the formation of non-toxic nitrate, the reaction of O_2^- with $\cdot\text{NO}$ was later recognized to yield a reactive intermediate, ONOO^- , which could exert profound biological effects (Beckman, 1990; Beckman *et al.*, 1993; Radi *et al.*, 1991a).

The biological formation of peroxynitrite¹ has been demonstrated at cell and tissue levels under different pathophysiological conditions. Both ONOO^- and its protonated form, peroxynitrous acid (ONOOH), are strong biological oxidants that can cause a variety of alterations on cell and tissue homeostasis. The interactions of peroxynitrite with cell components result in severe dysfunction and can ultimately lead to cell death (Denicola *et al.*, 1993; Estevez *et al.*, 1995; Lin *et al.*, 1995; Zhu *et al.*, 1992).

In this chapter we analyze the chemical and biological properties of peroxynitrite that make this molecule pathologically relevant. In addition, we aim to provide a sound biochemical background for the development of pharmacological interventions against the toxic actions of peroxynitrite *in vivo*.

Peroxynitrite Formation Pathways

Reaction of Nitric Oxide with Superoxide

The radical species $\cdot\text{NO}$ and O_2^- can be formed endogenously and can readily interact with each other to yield peroxynitrite.

¹ Throughout the text, the name peroxynitrite is used to refer to both peroxynitrite anion (ONOO^-) and peroxynitrous acid (ONOOH). IUPAC recommends the names nitrogen monoxide for $\cdot\text{NO}$ (nitric oxide), oxoperoxynitrate(1-) for ONOO^- (peroxynitrite), and hydrogen oxoperoxynitrate for its conjugated acid, ONOOH (peroxynitrous acid).

O_2^- is the one-electron reduction product of dioxygen. It can be formed through enzymes such as NADPH oxidase and xanthine oxidase, through the redox cycling of xenobiotics, via electron leakage in the mitochondrial respiratory chain, and at the endoplasmic reticulum (Freeman and Crapo, 1982; Turrens and Boveris, 1980). The main route of O_2^- consumption in biological systems is the superoxide dismutase (SOD)-catalyzed dismutation to hydrogen peroxide (H_2O_2) and dioxygen. O_2^- can also react with other targets such as iron sulfur clusters, transition metal centers, and sulfhydryls, but the rate constants of these reactions are $10^6 \text{ M}^{-1} \text{ s}^{-1}$ or lower. Thus, due mainly to the preferential reaction with SOD, the steady state concentrations of O_2^- are kept low, in the nanomolar to picomolar range (Chance *et al.*, 1979). However, the intracellular fluxes of O_2^- are significant (exceeding micromolar per second) due to the high respiration rates of most cells, and it is estimated that around 1% of the dioxygen respired evolves to O_2^- . This value can increase severalfold under conditions of altered cellular homeostasis and inflammatory processes.

$\cdot\text{NO}$ in biological systems has a half-life of several seconds (Ignarro, 1990; Moncada *et al.*, 1991). Since its reaction with dioxygen is relatively slow, the consumption of $\cdot\text{NO}$ is determined by its reactions with other targets such as transition metals, organic radicals, and O_2^- . $\cdot\text{NO}$ will react with heme proteins such as the enzyme guanylate cyclase, responsible for the signaling effects of $\cdot\text{NO}$, and with oxyhemoglobin. The rate constants of these reactions are approximately $10^7 \text{ M}^{-1} \text{ s}^{-1}$. $\cdot\text{NO}$ may also react with organic radicals such as tyrosyl or peroxy radicals with rate constants of $10^9 \text{ M}^{-1} \text{ s}^{-1}$ (Eiserich *et al.*, 1995; Padmaja and Huie, 1993).

The reaction rate between $\cdot\text{NO}$ and O_2^- to form peroxynitrite is near to the diffusion-controlled limit [Eq. (1)].

The rate constant for reaction (1) has been reported as $6.7 \times 10^9 \text{ M}^{-1} \text{ s}^{-1}$ (Huie and Padmaja, 1993) and $4.3 \times 10^9 \text{ M}^{-1} \text{ s}^{-1}$ (Goldstein and Czapski, 1995a). A more recent re-determination with less potentially interfering secondary reactions reported a rate constant of $1.9 \times 10^{10} \text{ M}^{-1} \text{ s}^{-1}$ (Kissner *et al.*, 1997). Thus, it is safe to assume a k value of $10^{10} \text{ M}^{-1} \text{ s}^{-1}$ for this reaction, a value five times higher than that of Cu,Zn-SOD ($2 \times 10^9 \text{ M}^{-1} \text{ s}^{-1}$). In fact, $\cdot\text{NO}$ is the only biomolecule known to react fast enough and to be produced at sufficient concentrations to outcompete SOD for its reaction with O_2^- . It can be calculated that at physiological concentrations of SOD ($\sim 10 \mu\text{M}$), a concentration of $2 \mu\text{M}$ $\cdot\text{NO}$ will react with about half of the O_2^- formed, yielding peroxynitrite. Whereas the steady-state concentration of $\cdot\text{NO}$ needed for exerting its messenger role is in the nanomolar range, in inflammatory sites $\cdot\text{NO}$ can reach micromolar concentrations (Moncada *et al.*, 1991), allowing for peroxynitrite formation to be kinetically feasible. It is useful to recall that for every 10-fold increase in $\cdot\text{NO}$ and O_2^- concentration, a 100-fold increase in the rate of peroxynitrite formation should occur (Beckman, 1996).

Other Routes

NITRIC OXIDE SYNTHASE

The enzyme nitric oxide synthase produces $\cdot\text{NO}$. However, under arginine depletion, O_2^- is concomitantly formed, promoting peroxynitrite formation, through the uncoupling of NADPH consumption from arginine oxidation. This process has been shown to occur both in isolated [endothelial NOS (eNOS), neuronal NOS (nNOS), and inducible NOS (iNOS)] as well as in iNOS-containing macrophages and in nNOS transfected kidney cells (Vasquez-Vivar *et al.*, 1998; Xia *et al.*, 1996, 1998a,b; Xia and Zweier, 1997).

REACTION OF NITROXYL ANION WITH DIOXYGEN

Nitroxyl anion [NO^- , oxonitrate(1-)] can be formed through the one-electron reduction of $\cdot\text{NO}$ [$E^\circ(\cdot\text{NO}/\text{NO}^-) = 0.39 \text{ V}$]. In turn, NO^- can react with O_2 , yielding peroxynitrite (Donald *et al.*, 1986).

Since NO^- could be formed biologically (Hogg *et al.*, 1996; Wong *et al.*, 1998; Wink *et al.*, 1998), its reaction with dioxygen may represent a secondary route of peroxynitrite formation *in vivo*. Indeed, peroxynitrite formation was suggested after reduction of $\cdot\text{NO}$ by mitochondrial ferrocytochrome *c* (Sharpe and Cooper, 1998a).

REACTIONS OF OXYMYOGLOBIN AND OXYHEMOGLOBIN WITH $\cdot\text{NO}$

The reaction of $\cdot\text{NO}$ with oxymyoglobin or oxyhemoglobin [$k = 3 \times 10^7 \text{ M}^{-1} \text{ s}^{-1}$ (Doyle and Hoekstra, 1981)] leads to nitrate. It has been proposed that this occurs through the formation of an intermediate peroxynitrite (Herold, 1999; Ignarro, 1990; Wade and Castro, 1996).

Physicochemical Properties

Thermodynamic Properties

Thermochemical calculations on peroxynitrite are based on two experimentally determined values. First, the enthalpy of formation of peroxynitrite was determined as $-10 \pm 1 \text{ kcal mol}^{-1}$ by calorimetric measurements of its decomposition to nitrate ($-39 \pm 1 \text{ kcal mol}^{-1}$) (Bohle *et al.*, 1994; Manuszak and Koppenol, 1996). Second, the enthalpy of peroxynitrous acid ionization was considered close to zero (Koppenol *et al.*, 1992) and recently was redetermined as $4 \pm 2 \text{ kcal mol}^{-1}$ (Koppenol and Kissner, 1998). In order to estimate the Gibbs energy of formation, the absolute entropy of peroxynitrite must be evaluated. Different authors have made discrepant estimations, leading to controversy regarding the possible pathways of peroxynitrite decomposition (Koppenol and Kissner, 1998; Koppenol *et al.*, 1992; Merenyi and Lind, 1997). Nevertheless, there is agreement that

peroxynitrite is an oxidizing molecule, with estimated one- and two-electron reduction potentials of $E^\circ(\text{ONOOH}, \text{H}^+/\text{NO}_2, \text{H}_2\text{O}) = 1.6\text{--}1.7 \text{ V}$ and $E^\circ(\text{ONOOH}, \text{H}^+/\text{NO}_2^-, \text{H}_2\text{O}) = 1.3\text{--}1.37 \text{ V}$ (Koppenol and Kissner, 1998; Merenyi and Lind, 1997).

The activation parameters of peroxynitrite decomposition to nitrate were initially reported as $18 \pm 1 \text{ kcal mol}^{-1}$ for the activation enthalpy, $3 \pm 2 \text{ cal mol}^{-1} \text{ K}^{-1}$ for the activation entropy (Alvarez *et al.*, 1995; Koppenol *et al.*, 1992), and $1.7 \pm 1.0 \text{ cm}^3 \text{ mol}^{-1}$ for the activation volume (Kissner *et al.*, 1997). More recently, values of $21.2 \text{ kcal mol}^{-1}$, $+13 \text{ cal mol}^{-1} \text{ K}^{-1}$, and $+10 \text{ cm}^3 \text{ mol}^{-1}$, respectively, were reported (Goldstein *et al.*, 1999; Merenyi, *et al.*, 1999). These values have been discussed in terms of the mechanisms of peroxynitrite decomposition (Pryor and Squadrito, 1995).

Conformation

The possible conformations of peroxynitrite have been proposed based on quantum calculations and spectral data. According to the former, the bond between the nitrogen and the peroxidic oxygen has a partial double bond character. Around this bond, a *cis* and a *trans* conformer can be defined.

For peroxynitrite anion, the *cis* conformer would be more stable than the *trans* by $3\text{--}4 \text{ kcal mol}^{-1}$. For peroxynitrous acid, the *cis* would also be more stable, by $1\text{--}2 \text{ kcal mol}^{-1}$ (Tsai *et al.*, 1996; Tsai *et al.*, 1994). There is no agreement on whether the rate of interconversion between the conformers is fast or slow, and the importance of these conformers for peroxynitrite chemistry is under debate (Pryor and Squadrito, 1995). Since the calculated barrier for interconversion between the *cis* and the *trans* anions would be $21\text{--}24 \text{ kcal mol}^{-1}$, and $10\text{--}12 \text{ kcal mol}^{-1}$ lower for the acids, it has been proposed that ONOO^- would predominate as the *cis* conformer; hydration would enable it to switch to the more unstable *trans* and decompose (Tsai *et al.*, 1996; Tsai *et al.*, 1994). X-ray analysis suggests that peroxynitrite crystallized in the *cis* form (Worle *et al.*, 1999).

Spectral Properties

ULTRAVIOLET-VISIBLE SPECTROSCOPY

The absorption spectrum of ONOO^- in the ultraviolet (UV) region consists of a single rather broad band centered at 302 nm in aqueous alkaline solution (Hughes and Nicklin, 1968). The maximum at 302 nm has been universally used to quantify peroxynitrite using the ϵ value reported by Hughes and Nicklin of $1670 \pm 50 \text{ M}^{-1} \text{ cm}^{-1}$. More recently, Bohle *et al.* (1994) reported a more accurate value of $1700 \pm 10 \text{ M}^{-1} \text{ cm}^{-1}$. Nevertheless, the former value is still the most widely used.

The UV absorption of ONOO^- has been studied in detail in nonaqueous media such as solid argon matrixes at 12 K (Lo *et al.*, 1995), dichloromethane, or liquid ammonia (Bohle *et al.*, 1996). In these experiments it has been shown

that in non-hydrogen-bonding solvents and in solid ONOO⁻ absorption is greatly red-shifted, indicating that peroxyntirite is greatly stabilized in aqueous solution through solvent interactions.

VIBRATIONAL SPECTRA

Infrared and Raman spectra of ONOOH and ONOO⁻ have been obtained Cheng, 1991; Bohle *et al.*, 1994; Tsai *et al.*, 1994, #1053]. The bands are wide, suggesting interaction with water. However, the interpretation of vibrational spectra is not straightforward and the results do not clarify the issue of peroxyntirite conformers.

NUCLEAR MAGNETIC RESONANCE

¹⁵N NMR experiments with peroxyntirite in basic aqueous solutions show the presence of only one peak at 191.4 ppm from nitrate (Bohle *et al.*, 1994; Tsai *et al.*, 1996). This was interpreted as indicative of only one conformer being present in solution or of rapid interconversion between the *cis* and *trans* conformers.

Acid-Base Properties

Peroxyntirous is a weak acid. Since it decays relatively fast, its ionization constant (K_a) cannot be measured directly. Thus, most reports on the pK_a of peroxyntirous acid are based on kinetic measurements of peroxyntirite decomposition in phosphate buffer (see following). There is agreement in the literature on a pK_a value of 6.8.

At the physiological pH of 7.4, both ONOO⁻ and ONOOH will be present, in proportions of 80 and 20%, respectively.

The decomposition of peroxyntirite can be affected by the concentration and the nature of the buffer. At low phosphate concentrations the pK_a can decrease from 6.8 to 6.5 (Kissner *et al.*, 1997), and in the presence of HEPES, CAPS, CAPSO, formate, borate, or ammonia the apparent pK_a increases to values near 8 (Beckman, 1996; Koppenol, 1998). Furthermore, reaction of peroxyntirite with the buffers can occur in some cases (Gadella *et al.*, 1997).

In addition to the proton, other Lewis acids catalyze peroxyntirite decomposition, such as transition metals (Beckman *et al.*, 1992; Ferrer-Sueta *et al.*, 1997), aldehydes (Uppu *et al.*, 1997), and carbon dioxide (Denicola *et al.*, 1996; Lyman and Hurst, 1995). In the process, reactive intermediates are formed.

Biochemical Reactivity

Peroxyntirite formed in a biological system can have different possible fates. In fact, its high reduction potential indicates that it could oxidize a wide variety of biomolecules. Thus, in order to understand the effects of peroxyntirite formation in biological systems, it is important to characterize the kinetics of peroxyntirite reactions with biomolecules.

In contrast to extremely reactive biological oxidants such as the hydroxyl radical ($\cdot\text{OH}$), whose high rate of reaction with most molecules ($>10^9 \text{ M}^{-1} \text{ s}^{-1}$) determines that it will react nonspecifically and close to its site of formation, peroxyntirite reactions are relatively slow. Thus, peroxyntirite will be more selective in its target molecules and will be able to react relatively distant to its site of formation.

Approach to the Study of Peroxyntirite Reactivity

DIRECT STUDIES

Since peroxyntirite decomposition at neutral pH and 37°C occurs in less than 10 s, in order to study the kinetics of peroxyntirite reactions special techniques need to be used. The stopped-flow spectrophotometer has a fast mixing device that allows it to study reactions that occur in a time scale of milliseconds. Peroxyntirite absorption at 302 nm can be used to follow the reactions, and both integral or initial rate approaches can be designed (Alvarez *et al.*, 1999; Floris *et al.*, 1993; Radi *et al.*, 1991a).

COMPETITION STUDIES

When parallel reactions yield different products, it can be shown that the ratio of these products will be proportional to the relative rate of the reactions [Eqs. (5)–(7)].

$$\frac{[\text{P}_1]}{[\text{P}_2]} = \frac{k_1 [\text{A}_1]}{k_2 [\text{A}_2]} \quad (7)$$

Thus, the ratio of the rate constants can be deduced from the ratio of products formed. This approach has been used to determine the kinetics of peroxyntirite reaction with one target by measuring the amount of product formed in the presence of competing scavengers of known reactivity (Castro *et al.*, 1994; Souza and Radi, 1998).

For instance, to measure the rate constant of the reaction of an enzyme (E) with peroxyntirite, it is possible to determine the activity of the enzyme alone and exposed to peroxyntirite in the presence of increasing concentrations of a peroxyntirite scavenger. Defining F_1 as the fraction of protection:

$$F_1 = \frac{A_s - A_p}{A_0 - A_p} \quad (8)$$

where A_0 is the enzymatic activity in the absence of peroxyntirite, A_p is in its presence, and A_s is the activity when a concentration [S] of scavenger was added, it can be shown that (Winterbourn, 1987)

$$\frac{F_1}{1 - F_1} = \frac{k_s[\text{S}]}{k_E[\text{E}]} \quad (9)$$

where k_s and k_E are the rate constants with the scavenger and with the enzyme, respectively. Rearranging the equation, plots of $[F_1/(1 - F_1)](1/k_s)[\text{E}]$ versus [S] can be drawn. The slope of such plots represents $1/k_E$.

However, the competition approach should be used with caution. The scavengers present in excess may reduce a target molecule that was previously oxidized by peroxynitrite. Besides, secondary scavenger-derived reactive species may be formed and further react with the target. Finally, it is important to point out that at low target concentrations three processes will actually be competing. In addition to reacting with the target and with the scavenger, a significant fraction of peroxynitrite will decompose via the proton-catalyzed decomposition to nitrate, yielding reactive intermediates as described later.

Peroxynitrite Decomposition in the Absence of Targets

Peroxynitrite is relatively stable in alkaline solution. However, at neutral or acidic pH it decomposes fast. The absorbance at 302 nm then decreases following an exponential function (Radi *et al.*, 1991a). The rate constant of peroxynitrite decomposition at pH 7.4 is 0.26 s^{-1} at 25°C and 0.9 s^{-1} at 37°C . The rate of peroxynitrite decomposition increases at acidic pH with limiting rate constants of 1.3 and 4.5 s^{-1} at 25° and 37°C , respectively (Alvarez *et al.*, 1998; Koppenol *et al.*, 1992). From the half-maximum values, the equilibrium constant for peroxynitrous acid ionization was determined to be $\text{p}K_a = 6.8$ (Radi *et al.*, 1991a).

Keith and Powell (1969) proposed the following reaction scheme for the acid-catalyzed decomposition of peroxynitrite:

According to this scheme, the apparent rate constant of peroxynitrite decomposition (k) would follow the equation:

$$k = \frac{k_{\text{HA}}[\text{H}^+]}{K_a + [\text{H}^+]} \quad (12)$$

where k_{HA} is the pH-independent rate constant.

The final product of the spontaneous decomposition of peroxynitrite at acidic pH is nitrate (Anbar and Taube, 1954; Bohle and Hansert, 1997). However, at alkaline pH peroxynitrite also decomposes to nitrite with about 30% yield at pH 7.5, with the concomitant production of dioxygen (Pfeiffer *et al.*, 1997; Radi *et al.*, 1991b).

Mechanism of Peroxynitrite Isomerization to Nitrate

There are two mechanistically feasible pathways by which peroxynitrous acid can isomerize to nitrate (Koppenol *et al.*, 1992). The first is homolysis to $\cdot\text{NO}_2$ and $\cdot\text{OH}$ followed by reaction of the radicals to form nitrate; the second is internal rearrangement of *trans*-peroxynitrous acid to nitric acid.

Homolysis of peroxynitrous acid has been the subject of debate. The proposal of potential formation of $\cdot\text{OH}$ from

peroxynitrite (Beckman *et al.*, 1990; Radi *et al.*, 1991b) was received with interest because it provided a mechanism that was independent of transition metals for the formation of this extremely potent oxidant [$E^\circ(\cdot\text{OH}, \text{H}^+/\text{H}_2\text{O}) = 2.3 \text{ V}$] (Koppenol, 1989), whereas the mechanisms previously proposed depended on the interaction of hydrogen peroxide with free or protein-bound transition metals.

Homolysis would imply the initial formation of the radicals in a solvent cage (Pryor and Squadrito, 1995). The radicals would recombine inside the cage or diffuse. This proposal was raised after the fact that it was possible to trap only a fraction of peroxynitrite as $\cdot\text{OH}$ became known (caged radicals are untrappable by definition). Alternatively, it has been proposed that ONOOH rearranges into nitrate via the formation of a reactive intermediate, a vibrationally distorted *trans* peroxynitrous acid or a hydrogen-bonded radical pair ($\text{OH}\cdots\text{ONO}$) (Houk *et al.*, 1996; Koppenol *et al.*, 1992).

Different approaches have been used to address the question of the pathway of peroxynitrite isomerization: thermochemical calculations (Koppenol and Kissner, 1998; Koppenol *et al.*, 1992; Merenyi and Lind, 1997), values of activation parameters for the isomerization reaction (Kissner *et al.*, 1997; Koppenol *et al.*, 1992; Goldstein *et al.*, 1999; Merenyi *et al.*, 1999), experiments varying the viscosity of the solvent (Pryor *et al.*, 1996), experiments with water isotopically labeled in the hydrogen or in the oxygen (Anbar and Taube, 1954; Bohle and Hansert, 1997; Koppenol, 1998), electronic paramagnetic resonance spectroscopy (Augusto *et al.*, 1994; Gatti *et al.*, 1998; Lemerrier *et al.*, 1995; Pou *et al.*, 1995), competition and product analysis in the presence of hydroxyl radical scavengers (Beckman *et al.*, 1990) (Alvarez *et al.*, 1995; Augusto *et al.*, 1994; Beckman *et al.*, 1990; Goldstein and Czapski, 1995b; Lyman and Hurst, 1998a; Gerasimov and Lyman, 1999; Coddington *et al.*, 1999; Richeson *et al.*, 1998), and quantum-mechanical calculations (Houk *et al.*, 1996; Jursic *et al.*, 1997).

Overall, the results favor the hypothesis of homolysis. In this sense, electronic paramagnetic resonance (EPR) spin-trapping experiments have shown that in the presence of the spin trap 5,5-dimethyl-1-pyrroline *N*-oxide (DMPO), the DMPO-hydroxyl radical adduct is formed (Augusto *et al.*, 1994; Gatti *et al.*, 1998). The formation of the adduct is inhibited by formate and ethanol, as expected from their rate constants with $\cdot\text{OH}$, with concomitant formation of the predicted trapped products. Experiments with ^{17}O -labeled water confirmed that the $\cdot\text{OH}$ trapped by DMPO came from the peroxynitrite molecule, not the solvent.

Thus, in the pathway of peroxynitrite isomerization to nitrate, highly reactive $\cdot\text{OH}$ and $\cdot\text{NO}_2$ radicals are formed. We will refer to it throughout the text as the “hydroxyl radical pathway.”

Peroxynitrite Reaction with Target Molecules

Molecules that are present during peroxynitrite decomposition can react with it through two main pathways

that have been proposed on the basis of kinetic studies (Fig. 1).

In one pathway (Fig. 1, I and II), ONOO^- or ONOOH reacts directly with the target in processes that are second order overall: first order in peroxynitrite and first order in the target, so that the apparent rate constant of peroxynitrite decomposition increases linearly with target concentration (Fig. 2). In the other pathway (Fig. 1, III), ONOOH first rearranges into $\cdot\text{OH}$ and $\cdot\text{NO}_2$, which are the ultimate oxidants. These processes are first order in peroxynitrite and

zero order in target (Fig. 2), since the formation of the radicals would be the rate-limiting step. However, in some cases, the plots of the apparent rate constant of peroxynitrite that decay as a function of target concentration are more complex (Alvarez *et al.*, 1999; Gatti *et al.*, 1998; Pryor *et al.*, 1994).

Peroxynitrite can perform both two- and one-electron oxidations to target molecules. The latter process leads to the formation of free radicals (Bartlett *et al.*, 1995; Gatti *et al.*, 1994; Pietraforte and Minetti, 1997a,b), which can in turn initiate radical chain reactions. In some cases, the formation

Figure 1 Pathways of peroxynitrite decomposition and reduction. Peroxynitrite can cause the oxidation of target molecules (S1) via direct reactions (I) or it can react with CO_2 to form ONOOCO_2^- (II). In the absence of direct targets, peroxynitrite slowly evolves to hydroxyl radical and nitrogen dioxide which can oxidize/nitrate other targets (S2) (III) or isomerize to nitrate (IV).

Figure 2 Peroxynitrite reaction with target molecules. In one pathway peroxynitrite reacts directly with the target molecule in an overall second-order process (top). In the other pathway peroxynitrite first decomposes into hydroxyl radical and nitrogen dioxide, which are the ultimate oxidants in a process that is zero order in the target (bottom).

of the one-electron oxidation product has been related to the hydroxyl radical pathway (Padmaja *et al.*, 1996a; Pryor *et al.*, 1994; Quijano *et al.*, 1997).

Direct Reactions

The second-order rate constants of peroxynitrite reaction with a number of molecules have been determined and are collected in Table I. Both ONOO[−] and ONOOH can undergo second-order reactions and in most cases the apparent rate

constants at pH 7.4 are reported in Table I. Those reactions that are most important from a biochemical point of view will be described in detail following.

THIOLS

The reaction with the thiol groups of cysteine and albumin was the first reaction of peroxynitrite with a biomolecule studied by stopped-flow (Radi *et al.*, 1991a). Since then a number of reports on other low-molecular-weight sulfhydryls have been produced, all of them with rate constants in

Table I Second-Order Rate Constants of Peroxynitrite Reaction with Biologically and Pharmacologically Relevant Target Molecules

Figure 4 Kinetics of peroxynitrite reaction with amino acids. Apparent rate of peroxynitrite decomposition in the presence of increasing concentrations of the free L-amino acids.

horseradish peroxidase can use peroxynitrite as a substrate and then be reduced by endogenous reductants.

The iron–sulfur cluster in aconitase (Castro *et al.*, 1994; Hausladen and Fridovich, 1994) and the Zn–S active site of yeast alcohol dehydrogenase (Crow *et al.*, 1995) are also oxidized by peroxynitrite, but in this case the oxidation causes the disruption of the active site and the loss of enzymatic activity.

THE PEROXYNITRITE–CO₂ REACTION

Reaction Chemistry Early work pointed out the instability of peroxynitrite in carbonated buffers (Keith and Powell, 1969). Recent studies have shown that the bicarbonate–carbon dioxide pair has strong influence on peroxynitrite reactivity and kinetics (Denicola *et al.*, 1996; Goldstein and Czapski, 1997; Gow *et al.*, 1996; Lemerrier *et al.*, 1997; Lyman and Hurst, 1995, 1996, 1998b; Lyman *et al.*, 1996; Pryor *et al.*, 1997; Radi *et al.*, 1993; Uppu *et al.*, 1996a; van der Vliet *et al.*, 1994; Zhang *et al.*, 1997).

Peroxynitrite decomposition in the presence of bicarbonate–carbon dioxide follows second-order kinetics (Denicola *et al.*, 1996; Lyman and Hurst, 1995; Uppu *et al.*, 1996a). The pH dependency of the reaction rate shows a bell-shape profile with a maximum at 6.5, indicating that ionization of both peroxynitrite and bicarbonate (apparent pK_a at 37°C is 6.1) contributes to the pH profile. pH jump (Lyman and Hurst, 1995) and carbonic anhydrase experiments (Uppu *et al.*, 1996a) have shown that the reacting species are ONOO[−] and CO₂. The pH-independent second-order rate constant for the peroxynitrite–CO₂ reaction is $5.8 \times 10^4 \text{ M}^{-1} \text{ s}^{-1}$ at 37°C (Denicola *et al.*, 1996). Considering the relatively high concentration of CO₂ both in intra- and extracellular compartments (1–2 mM), its reaction with ONOO[−] becomes one of the fastest for peroxynitrite in biological systems.

Reactivity of the ONOOCO₂[−] Adduct The product of the peroxynitrite–CO₂ reaction is the adduct ONOOCO₂[−] (1-carboxylate-2-nitrosodioxidane), which rapidly decomposes to CO₂ and nitrate. The short half-life of ONOOCO₂[−]

(< 1 μs) is attributable to the presence of a weak O–O bond (Merenyi and Lind, 1997).

In the absence of target molecules, CO₂ catalyzes the decomposition of peroxynitrite to nitrate at a higher rate than the proton-catalyzed isomerization (i.e., 46 versus 0.9 s^{−1} at 1 mM CO₂ and pH 7.4). However, CO₂ can not be considered a “scavenger” of peroxynitrite because the ONOOCO₂[−] adduct is not an inert species. In the presence of substrates, the adduct can perform one-electron oxidations as well as nitrations but with a reactivity different than peroxynitrite itself. In general the ONOOCO₂[−] adduct is a less potent oxidant but a more powerful nitrating agent than peroxynitrite itself (Denicola *et al.*, 1996; Goldstein and Czapski, 1997; Lemerrier *et al.*, 1997; Lyman and Hurst, 1995, 1996, 1998b; Pryor *et al.*, 1997; Radi *et al.*, 1999; Uppu *et al.*, 1996a). This is due to the homolytic decomposition to yield carbonate radical (CO₃^{•−}) and nitrogen dioxide (NO₂[•]) as the main pathway (Fig. 5). The formation of CO₃^{•−} has been indirectly detected by photochemical (Denicola *et al.*, 1996) and product distribution studies (Lyman and Hurst, 1998b) and more recently directly by EPR (Bonini *et al.*, 1999). Carbonate radical is a reactive species able to oxidize biomolecules with rate constants in the range of 10⁵–10⁸ M^{−1} s^{−1} (Chen and Hoffman, 1973; Chen and Hoffman, 1974) (e.g., $5 \times 10^7 \text{ M}^{-1} \text{ s}^{-1}$ with tyrosine).

Maximum oxidation or nitration yields by the adduct are on the order of 20–35% (Goldstein and Czapski, 1997; Lyman and Hurst, 1998b) on line with the initial formation of CO₃^{•−} and •NO₂ as a caged radical pair (Fig. 5).

The differential chemical reactivity of ONOOCO₂[−] and its significantly shorter half-life compared to ONOO[−] (~1s versus <1 μs at pH 7.4) determine that (a) the presence of carbon dioxide redirects peroxynitrite reactivity and (b) the adduct can diffuse a significantly shorter distance than peroxynitrite in biological milieu.

Reactions via the Hydroxyl Radical Pathway

Among relevant targets that have been reported to react with the •OH arising from peroxynitrite homolysis are phenolics such as 4-hydroxyphenylacetic acid (Beckman *et al.*, 1992), tyrosine, phenol, and salicylate (Ramezani *et al.*, 1996); phenylalanine (van der Vliet *et al.*, 1994); histidine (Alvarez *et al.*, 1999); hydrogen peroxide (Alvarez *et al.*, 1995); deoxyribose (Beckman *et al.*, 1990); mannitol; ethanol (Alvarez *et al.*, 1998); ubiquinol (Schöpfer *et al.*, 2000); and lipids (Radi *et al.*, 1991b; Shustov *et al.*, 2000).

The oxidation yield of these processes was found to be less than 30% of the peroxynitrite added, even when the values were extrapolated to infinite substrate concentration (Beckman *et al.*, 1990).

When the one-electron oxidation product of the target leads to O₂^{•−} formation, such as in the case of hydrogen peroxide and ethanol, peroxynitrate (O₂NOO[−]) may be formed

Figure 5 Formation of carbonate radical from $\text{ONO}_2\text{CO}_2^-$ adduct decomposition.

from the reaction of O_2^- and $\cdot\text{NO}_2$ (Alvarez *et al.*, 1995; Goldstein and Czapski, 1998; Hodges and Ingold, 1999).

NITRATION

Peroxynitrite is a good nitrating agent for aromatic compounds (e.g., tyrosine, tryptophan). At 25°C and neutral pH peroxynitrite-mediated tyrosine nitration in phosphate has a maximum yield of 6–8% nitrotyrosine formed with respect to peroxynitrite (Ischiropoulos *et al.*, 1992a). Tyrosine is nitrated without affecting the rate of peroxynitrite decomposition, indicating that $\cdot\text{OH}$ and $\cdot\text{NO}_2$ are responsible for this reaction (Ramezani *et al.*, 1996). The formation of bityrosine as a side product during the nitration reaction is a clear indication of a radical mechanism (van der Vliet *et al.*, 1995). The reaction is complex and involves many competing reactions:

It can be seen that the yield of nitrotyrosine [reaction (18)] depends on pH [through reaction (15)] and the relative concentrations of peroxynitrite and tyrosine [through reactions (17) to (19)] and on the concentrations of radicals formed and its side reactions [reactions (20) and (21)] (Goldstein *et al.*, 2000; Pfeiffer *et al.*, 2000). The overall nitration mechanism can be summarized as a one-electron oxidation of the aromatic ring [reaction (17) and (19)] followed by a coupling of the resulting phenoxyl radical with nitrogen di-

oxide. The first reaction is H^+ -catalyzed, as the yield of nitration decreases at alkaline pH.

Besides H^+ , other Lewis acids (LA) including CO_2 and transition metal centers (Table II) catalyze peroxynitrite-mediated tyrosine nitration. In general the reaction can be represented as:

where $\text{LA}-\text{O}^\cdot$ is the oxidizing intermediate (Table II).

Nitration yields as a function of initial peroxynitrite added vary widely depending on the Lewis acid (Table II).

It can be seen from Table II that the redox potential of the oxidizing intermediate is an important factor in determining the nitration yield in the presence of catalysts.

Direct Reactions versus the Hydroxyl Radical Pathway

When peroxynitrite reacts directly with a target molecule, the rate of the reaction will be proportional to the product of the rate constant times the concentration (Fig. 6). On the other hand, when the oxidant is the $\cdot\text{OH}$, the apparent rate of this process is the proton-catalyzed decomposition of peroxynitrite: 0.9 s^{-1} at pH 7.4 and 37°C. In biological systems, it can be calculated that most peroxynitrite will be consumed by direct reactions. The contribution of the hydroxyl radical pathway to peroxynitrite reactivity in biology is a rather minor route (<5%); peroxynitrite will react before evolving to secondary reactive intermediates (Fig. 6).

Diffusion

Oxidizing intermediates tend to have limited diffusion in the biological milieu because of their high reactivity toward biomolecules, which determines that most of the oxidant will

be consumed within the compartment where it is formed. A striking example of this concept is the case of ·OH that reacts within three to four molecular diameters from its site of formation (Hutchinson, 1957).

Thus, to account for the biological actions of peroxynitrite, it becomes important to define how far it can diffuse and reach critical cellular targets. A related question is whether the cellular membrane is permeable to this oxidant.

Early evidence suggested that peroxynitrite was able to cross cell membranes, as intact cells exposed to peroxynitrite exhibited oxidation of intracellular proteins and inactivation of enzymes, indirectly indicating the ability of peroxynitrite to permeate membranes (Denicola *et al.*, 1993; Hu *et al.*, 1994; Radi *et al.*, 1994; Rubbo *et al.*, 1994a; Soszynski and Bartosz, 1996; Szabo *et al.*, 1996).

Mechanisms of Peroxynitrite Diffusion

Recent studies have directly proved the ability of peroxynitrite to diffuse across biological membranes (Denicola *et al.*

Figure 6 Direct reaction versus the hydroxyl radical pathway. As the concentration of target molecules that react directly with peroxynitrite increases, peroxynitrite will react preferentially with them instead of evolving to ·OH and ·NO₂ and isomerizing to nitrate.

et al., 1998; Marla *et al.*, 1997). Using model phospholipid vesicular systems, it has been demonstrated that peroxynitrite freely crosses phospholipid membranes (Marla *et al.*, 1997). Diffusion of peroxynitrite from extra- to intracellular compartments was also demonstrated using red blood cells as a model (Denicola *et al.*, 1998). Peroxynitrite can cross the erythrocyte membrane by a mechanism involving ONOO⁻ transport through the HCO₃⁻/Cl⁻ exchanger (band 3) and also by passive diffusion of ONOOH (Denicola *et al.*, 1998). At physiological pH, most peroxynitrite would be in the anionic form and therefore diffusion through the anion channel becomes relevant. Red blood cells are particularly abundant in this anion channel (band 3) but there are also proteins homologous to band 3 in nonerythroid cells that promote anion transport and that might serve to transport ONOO⁻ as well (Jennings, 1989). Superoxide anion also diffuses across membranes through the erythrocyte anion channel (Lynch and Fridovich, 1978). However, a significant difference is that passive diffusion of its conjugated acid HO₂[·] (pK_a = 4.8) is not feasible at physiological pH. In contrast, membranes scarce in anion channels and cellular compartments under low pH conditions will still be permeable to ONOOH.

While peroxynitrite is diffusing through the membrane, it can also react with some of its components, resulting in protein and/or lipid oxidation. For instance, in red blood cells nitration of the cytoplasmic domain of band 3 was observed at high concentrations of the oxidant (Mallozzi *et al.*, 1997). Thus, appropriate membrane targets can interact with a fraction of the peroxynitrite travelling across cell compartments.

Peroxynitrite Diffusion in Biology

The reported studies of peroxynitrite diffusion across membranes (Denicola *et al.*, 1998; Marla *et al.*, 1997) have been performed under conditions in which the decay of peroxynitrite in the extracellular milieu was only due to the proton-catalyzed decomposition, a relatively slow process in the diffusional time scale. However, from a biological perspective, an important question is whether the presence of

extracellular targets that will accelerate the consumption of peroxynitrite would preclude its diffusion to intracellular compartments. For instance, the reaction between peroxynitrite and CO_2 represents a major route of peroxynitrite consumption in biological systems, particularly in extracellular compartments. However, the diffusion of peroxynitrite across cells can occur even in the presence of extracellular CO_2 (Romero *et al.*, 1999). The concept is that the apparent rate of peroxynitrite diffusion across membranes can be comparable to and even larger than the rate of peroxynitrite reaction with CO_2 and other bioreductants (Fig. 7). Whereas at low cell densities the diffusion time of peroxynitrite will be too long to compete with extracellular target molecule reactions, at high cell densities the diffusion distances will be shorter and so an important percentage of peroxynitrite can reach and cross the membranes. For example, peroxynitrite production by activated macrophages can reach a pathogen cell and cause cytotoxic effects.

Biological Targets

Peroxynitrite reacts with a limited number of targets *in vivo* (Radi, 1998). This is due in part to the large variation of rate constants in the reactions of peroxynitrite against biological targets (Table I) and target concentrations. In addition, the formation sites of peroxynitrite differ depending on cell types, tissues, and pathophysiological conditions and therefore compartmentalization and diffusion proper-

ties of peroxynitrite also play a central role in determining the biological fate and principal reactions of this reactive intermediate.

Even though we still have partial information regarding the biological targets of peroxynitrite, we will describe some well-established events, which show some of the central pathways of peroxynitrite reactivity *in vivo* which account for its biological actions.

Proteins

Proteins are key biological targets of peroxynitrite due to their ubiquity, their concentration and the reactivity of some of their constituent amino acids and prosthetic groups.

Some predictions can be made regarding the reactivity of peroxynitrite toward proteins and peptides:

1. Transition metal centers such as reduced heme and metal-sulfur clusters will determine the rate constants when present.
2. Cysteine, methionine, and tryptophan (in that order) will account for the vast majority of the reactivity of the polypeptide.
3. The protein environment can enhance the reactivity of cys, met, and trp in proteins [such as the essential thiol in GAPDH (Souza and Radi, 1998)].
4. Selenium-containing amino acids (selenocysteine and selenomethionine) have enhanced reactivities respective to their sulfur analogs (Briviba *et al.*, 1996; Padmaja *et al.*, 1996a, 1997; Sies *et al.*, 1998).

Figure 7 Scheme representing competition between peroxynitrite diffusion and reaction with extracellular CO_2 .

5. Tyrosine nitration is a slow process and must be catalyzed by CO₂ or metals to occur *in vivo*.

ENZYME MODIFICATION

A number of enzymes are inactivated by reaction with peroxynitrite (Table III). The inactivations observed during exposure of the isolated enzyme have in many cases (Castro *et al.*, 1994, 1998), but not always (Cassina and Radi, 1996; Sharpe and Cooper, 1998b), been reproduced at the cellular or subcellular level where several other competing reactions exist.

Typically, peroxynitrite causes the irreversible oxidation or nitration of a critical residue in the protein. In contrast, in other cases the oxidation of the enzyme by peroxynitrite can be regarded as a step in the enzymatic cycle promoting the catalytic activity. Examples are prostaglandin endoperoxide synthase (Landino *et al.*, 1996) and several peroxidases (Floris *et al.*, 1993; Grace *et al.*, 1998; Sies *et al.*, 1997) that are oxidized by peroxynitrite and then reduced by endogenous substrates.

The only reported case of an enzyme activated by reaction with peroxynitrite is procollagenase (Okamoto *et al.*, 1997), in which peroxynitrite apparently oxidizes a cysteine residue in the autoinhibitory domain of the proenzyme, thus liberating a Zn coordination position in the active site and rendering the enzyme active.

It is important to remark that the “activation” of some enzymatic functions such as poly(ADP-ribose) synthetase (PARS) and caspase 3 during peroxynitrite exposure or formation *in vivo* (Cuzzocrea *et al.*, 1997; Endres *et al.*, 1998; Kennedy *et al.*, 1998; Lin *et al.*, 1998; Szabo *et al.*, 1996, 1997b) is not due to direct interactions of peroxynitrite with these enzymes, but rather to cellular responses associated with oxidative stress, and constitutes downstream events associated to peroxynitrite toxicity.

Enzyme Sensitivity and IC₅₀ Enzyme reactions with peroxynitrite are usually determined through the effect of the oxidant on enzyme activity. Peroxynitrite concentrations inhibiting 50% of initial enzyme activity (IC₅₀) are used as a

measure of the enzyme sensitivity to peroxynitrite (Castro *et al.*, 1994). Nevertheless, IC_{50} values do not provide a true measure of sensitivity unless they are determined with extreme care. Many factors influence IC_{50} , including enzyme concentration, stoichiometry of the reaction with peroxynitrite, the rate constants for the reaction of $ONOO^-$ with critical and noncritical residues in the enzyme, and the amount of peroxynitrite that escapes (via isomerization) during the reaction.

The following equation has been proposed to evaluate the rate constant of peroxynitrite reacting with an enzyme (Padmaja *et al.*, 1998):

$$[ONOO^-]_i = z(A_i - A_f)_E - \left(\frac{k_i}{k_E} \ln \frac{A_i}{A_f} \right) \quad (23)$$

where A_i and A_f are initial and final enzyme activities, z is the molar activity of the enzyme, k_i is the rate constant of peroxynitrite isomerization to nitrate, and k_E is the rate of the bimolecular reaction between peroxynitrite and the critical residue of the enzyme. This constant must not be confused with the overall rate constant of peroxynitrite with the whole protein molecule that is obtained through direct kinetic methods.

Equation (23) can be rearranged to give the dependence of IC_{50} on initial enzyme concentration.

$$IC_{50} = \frac{[E]_i}{2} + \frac{k_i}{k_E} \ln 2 \quad (24)$$

Thus, by determining IC_{50} values at different initial enzyme concentrations and plotting them as a function of $[E]_i$ the value of k_E can be obtained from the intercept.

The reaction stoichiometry and the protection of the enzyme by reaction of peroxynitrite with noncritical residues affect the slope of an IC_{50} versus $[E]_i$ plot; thus, a single determination of IC_{50} can lead to erroneous values of k_E .

A potential pitfall of this method is that it considers peroxynitrite as affecting only the turnover number of the enzyme. If the oxidation alters other enzymatic parameters, such as K_M and K_S (Forsmark-Andree *et al.*, 1996), the measurement of enzymatic activity might not yield reliable results if only one substrate concentration is used throughout the study. Another problem arises at low enzyme concentration because a significant fraction of peroxynitrite may evolve to $\cdot OH$ and $\cdot NO_2$, which may or may not affect enzyme activity.

In summary, k_E values are more reliable than IC_{50} for measuring the enzyme sensitivity to peroxynitrite, but they should be measured thoroughly over a range of high enzyme concentrations, and other enzymatic parameters should be considered.

PROTEIN NITRATION

Biological protein nitration is an event related to excess $\cdot NO$ production. Initially thought to depend exclusively on peroxynitrite reactions (Beckman *et al.*, 1994), it has more recently been shown that other biologically relevant mechanisms of protein nitration may exist. Some of these mecha-

nisms depend on the formation of nitrating species derived from interactions of hemeperoxidases with nitrite and peroxides (Eiserich *et al.*, 1998; van der Vliet *et al.*, 1997) and others on the oxidation of nitrosotyrosine with the intermediate formation of iminoxyl radicals (Gunther *et al.*, 1997).

Thus, since the formation of nitrotyrosine is not a totally specific "footprint" of peroxynitrite reactions, the accumulation of nitrated proteins can only be unambiguously attributed to a peroxynitrite-dependent mechanism with the aid of pharmacological tools.

Cellular Studies Indicating Peroxynitrite Formation and Protein Nitration For peroxynitrite to be formed, $\cdot NO$ and O_2^- should encounter each other in a given biological compartment. Since the biological half-lives and diffusion properties of $\cdot NO$ and O_2^- are rather different, with $\cdot NO$ being significantly longer lived and more diffusible than O_2^- , peroxynitrite formation will occur closer to the O_2^- -producing sites. Once generated, peroxynitrite can nitrate proteins in the same or adjacent cell or tissue compartments, as peroxynitrite can diffuse some distance in a cellular length scale (Denicola *et al.*, 1998).

The first study demonstrating cellular peroxynitrite-dependent nitration (Ischiropoulos *et al.*, 1992b) was performed in alveolar rat macrophages, in which $\cdot NO$ production by iNOS in concert with the formation of O_2^- by activation of the membrane-bound NADPH oxidase resulted in nitration of *p*-hydroxyphenylacetate present in the extracellular milieu. The nitration process was inhibitable by *N*-monomethyl arginine (L-NMMA). Externally added Cu,Zn-SOD was unable to inhibit nitration, possibly due to the fact that peroxynitrite was being formed in regions not readily accessible to SOD. In more recent studies in $\cdot NO$ - and O_2^- -producing macrophages, protein nitration was also detected intracellularly (Shigenaga *et al.*, 1997).

Other cellular models in which $\cdot NO$ and O_2^- were cogenerated also resulted in protein nitration (Estevez *et al.*, 1998; Estevez *et al.*, 1999, 2000). Growth factor deprivation and the presence of Zn-deficient SOD to rat embryo motor neurons induced protein nitration. Motor neuron nitration was inhibitable by either the NOS inhibitor L-nitroarginine methyl ester (L-NAME) or the cell permeable SOD mimic manganese(III) tetrakis(4'-benzoic acid)porphyrin (Mn-TBAP). Growth factor deprivation promoted the induction of nNOS, and excess O_2^- arose from a yet unidentified cellular source. The pharmacological inhibition of cellular nitration correlated with protection against cell death.

Normal human lymphocytes activated by antigen binding to the TCR/CD3 membrane complex and cultured in the presence of autologous monocytes presented protein tyrosine nitration (Brito *et al.*, 1999). Activated lymphocytes promoted the production of nitrating species by monocytes through soluble mediators such as cytokines or cell-to-cell interactions. The monocyte-derived nitrating species were able to nitrate their own cellular proteins and also cellular proteins of the neighboring lymphocytes. Nitration was almost completely inhibited by aminoguanidine, an inhibitor of the inducible isoform of nitric oxide synthase, or Mn-

TBAP. The combination of these two inhibitors completely abrogated nitrotyrosine detection in cellular proteins. These results indicate that peroxynitrite was the main nitrating agent and support the concept that peroxynitrite can diffuse from source to target cells.

Peroxynitrite-dependent intracellular nitration can be also seen during exposure of cells overproducing O_2^- to NO donors (Castro *et al.*, 1998). Hamster fibroblasts exposed to a low $\cdot NO$ flux had a small amount of intracellular protein nitration, which was attributable to the reactions of NO with the basal levels of endogenous O_2^- . When fibroblasts were poisoned to overproduce O_2^- at the mitochondrial electron transport chain, cellular nitration significantly increased. Exogenous addition of peroxynitrite also resulted in protein nitration, in agreement with the capacity of peroxynitrite to permeate membranes and react in different cell compartments. However, the nitration pattern observed in the Western blot analysis differed from that seen during exposure to the $\cdot NO$ donor, indicating that compartmentalization plays a role in targeting protein nitration. The critical role of glutathione in modulating nitration yields became evident in GSH-depleted fibroblasts. Indeed, cell depletion of GSH led to enhancement of protein nitration by peroxynitrite, indicating that GSH can trap, at least partially, nitrating intermediates arising from peroxynitrite, $ONOO^-$, and/or peroxynitrite-metal center adducts (Denicola *et al.*, 1996; Zhang *et al.*, 1997).

In conclusion, various cellular models responding to rather different stimuli which ultimately lead to $\cdot NO$, O_2^- , and then peroxynitrite formation, resulted in protein nitration. Nitration appears to be targeted to a restricted number of proteins and modulated by intracellular factors such as GSH. Identification of critical and preferentially nitrated proteins awaits further studies. Of note is the fact that the antioxidant enzyme Mn-superoxide dismutase that is located in the mitochondrial matrix is nitrated and inactivated *in vivo* during chronic rejection of human renal allografts (MacMillan-Crow *et al.*, 1996). This chronic inflammatory process progresses with an overproduction of both $\cdot NO$ and O_2^- , and targets nitration in a specific cellular compartment, affecting a specific protein function.

Lipid Peroxidation

Unsaturated membrane lipids are critical targets of oxygen-derived reactive species. O_2^- does not react at significant rates with polyunsaturated fatty acids (Bielski *et al.*, 1983), and O_2^- -mediated damage to membranes has been explained through the Haber-Weiss reaction [reactions (25) and (26)] which requires catalysis by transition metal ions (Girotti, 1985; Prutz *et al.*, 1985):

The mechanisms of lipid oxidation by reactive oxygen species involve initiation by $\cdot OH$ and propagation reactions involve oxygen consumption and formation and reactions of

peroxyl radicals (reactions *d* and *e*). End products of lipid peroxidation typically include lipid hydroperoxides, aldehydes, and other products derived from decomposition of unstable oxidized intermediates. Iron would further participate in lipid peroxidation processes by increasing the chain length of propagation by decomposing lipid hydroperoxides to either $LO\cdot$ and $LOO\cdot$ radicals in a chain-branching redox cycling mechanism:

Peroxynitrite is able to initiate lipid peroxidation. Indeed, in model membrane systems such as phosphatidylcholine liposomes, lipid peroxidation was evidenced by formation of malondialdehyde, conjugated dienes, oxygen consumption, and liquid chromatography-mass spectrometry (LC-MS) analysis of lipid hydroperoxides formation (Radi *et al.*, 1991b; Rubbo *et al.*, 1994b). Peroxynitrite oxidation of linolenic acid yields significant amounts of hydroperoxy- and hydroxy-linolenate (Rubbo *et al.*, 1994b).

Peroxynitrite initiated lipid peroxidation most effectively at acidic pH, which is consistent with $ONOOH$ rather than $ONOO^-$ as the oxidizing species (Radi *et al.*, 1991b; Shustov *et al.*, 2000). It is possible that lipid peroxidation also involves the participation of low concentrations of $\cdot NO_2$ or $\cdot NO$ produced in these reactions:

Hydroxyl radical reacts with unsaturated fatty acids at near diffusion-controlled rates ($k \approx 10^9 M^{-1} s^{-1}$) (Fig. 8, reaction *a*) and the $\cdot NO_2$ formed during $ONOOH$ decomposition is a lipophilic radical, capable of initiating fatty acid oxidation as well ($k = 10^5 M^{-1} s^{-1}$) by forming a carbon-centered alkyl radical (Fig. 8, reaction *b*). At low oxygen tensions, the carbon-centered alkyl radical combines with a second $\cdot NO_2$ to form allylic nitro (LNO_2) products (reaction *c*).

In addition, both $\cdot NO_2$ and $\cdot NO$ can react with peroxyl radicals to form $LOONO_2$ and $LOONO$, respectively, giving rise to nonradical end products of lipid peroxidation (reactions *f* and *g*). Indeed, in addition to the predominant hydroperoxy and hydroxy derivatives formed after treatment of linolenic acid with peroxynitrite, the formation of nitrogen-containing lipid species has been also evidenced (Rubbo *et al.*, 1994b). These products have been tentatively identified from their molecular weight as nitritolinolenate, nitrosoperoxolinolenate, hydroxynitrosoperoxolinolenate, and hydroperoxonitrosoperoxolinolenate. More recently, it was shown that the products of the reaction of peroxynitrite plus linoleic acid displayed mass/charge characteristics of nitrated lipid derivatives (O'Donnell, 1999). Some nitrogen-containing lipid intermediates appear to be highly unstable and may decompose to reinitiate radical processes. In particular, the product of the peroxyl radical/ $\cdot NO$ condensation reaction ($LOONO$) may be cleaved by homolysis (reaction

Figure 8 Scheme showing the major events occurring during peroxynitrite-dependent lipid oxidation.

h) to $\text{LO}\cdot$ and $\cdot\text{NO}_2$, with rearrangement of $\text{LO}\cdot$ to an epoxyallylic acid radical $\text{L}(\text{O})\cdot$ followed by recombination of $\text{L}(\text{O})\cdot$ with $\cdot\text{NO}_2$ (reaction i, [O'Donnell, 1999]).

Importantly, while iron is often required to initiate lipid peroxidation in many oxidizing systems, peroxynitrite induces lipid oxidation in model systems without the requirement of transition metals, since the metal chelator diethylenetriaminopentaacetic acid (DTPA) and iron depletion of reaction systems are only partially inhibitory (Radi *et al.*, 1991b).

Nucleic Acids

Peroxynitrite is able to cause significant DNA damage, including base modification, sugar oxidation, and strand breaks (Burney *et al.*, 1999).

On exposure of bases to peroxynitrite, several oxidative modifications were identified. The most reactive base seems to be guanine and the formation of 8-oxoguanine has been detected (Kennedy *et al.*, 1997a). 8-Oxoguanine is easily monitored for DNA damage and is known to cause GC-AT transitions. But further reaction of 8-oxoguanine with peroxynitrite may complicate its detection (Uppu *et al.*, 1996b). Remarkably, 8-nitroguanine has also been detected after peroxynitrite exposure (Yermilov *et al.*, 1995), which may be a useful marker of nucleic acid interactions with peroxynitrite. Most studies on peroxynitrite-dependent DNA damage have been conducted *in vitro* using nucleosides or isolated DNA. In addition, oxidative damage of bases has also been observed in the DNA of immunostimulated macrophages (deRojas-Walker *et al.*, 1995), as well as in spleen DNA of mice induced to produce high

levels of $\cdot\text{NO}$ (Nair *et al.*, 1998). These processes were prevented by NOS inhibitors.

Peroxynitrite can cause DNA strand breaks (King *et al.*, 1993), which have been detected both in isolated DNA (Salgo *et al.*, 1995a) and in cells exposed to exogenous peroxynitrite (Salgo *et al.*, 1995b). Mechanistically, the strand breaks seem to arise both from sugar damage and from base modification (Burney *et al.*, 1999). The formation of strand breaks has been shown to activate poly(ADP-ribose) synthetase (PARS), leading to NAD^+ consumption followed by energy depletion (Szabo and Ohshima, 1997).

Carbon dioxide increases formation of nitroguanine but decreases DNA strand breaks (Yermilov *et al.*, 1996) and it should be an important modulator of nucleic acid modifications by peroxynitrite *in vivo*.

Peroxynitrite in Action

The outcome observed after peroxynitrite interactions with cellular structures is a consequence of its physicochemical, biochemical, and toxicological properties. We will outline actions promoted by peroxynitrite in two rather different and relevant biostructures (mammalian mitochondria and low density lipoprotein), with the aim of integrating various aspects of the biological chemistry of peroxynitrite.

PEROXYNITRITE INTERACTIONS WITH MITOCHONDRIA

Peroxynitrite interactions with mitochondrial components account for much of the mitochondrial toxicity previously ascribed to $\cdot\text{NO}$ and it represents an important mechanism leading to mitochondrial dysfunction (Cassina and Radi, 1996; Lizasoain *et al.*, 1996; Radi *et al.*, 1994). Peroxynitrite present in mitochondria may arise from either direct diffusion from extramitochondrial compartments or from intramitochondrial formation. In turn, peroxynitrite inside the mitochondria is formed from mitochondrial O_2^- reacting either with $\cdot\text{NO}$ diffusing from the cytosol or with $\cdot\text{NO}$ formed by NOS that may be present in mitochondria (Giulivi *et al.*, 1998; Radi *et al.*, 1994).

At the mitochondrial electron transport chain, peroxynitrite causes inactivation of complex II (succinate dehydrogenase) and to a lesser extent complex I (NADH dehydrogenase) (Radi *et al.*, 1994); in addition it inactivates complex V (ATP synthase). Thus, peroxynitrite leads to a profound inhibition of electron transport and ATP synthesis (Richter *et al.*, 1999). It is important to remark that peroxynitrite does not affect complex IV-dependent respiration (cytochrome *c* oxidase) in intact mitochondria, in line with its known resistance to inactivation by biological oxidants (Zhang *et al.*, 1990). Moreover, reduced cytochrome *c* oxidase may decompose peroxynitrite by a two-electron redox reaction (Pearce *et al.*, 1999). Cytochrome *c* oxidase is sensitive to peroxynitrite only when reactions are carried out with the isolated complex IV (Sharpe and Cooper, 1998b), underscoring the importance of preferential competing reactions *in vivo*. In contrast, $\cdot\text{NO}$ readily interacts with the metal centers of cytochrome *a₃*, leading to reversible inhibition of

mitochondrial electron transfer and oxygen consumption (Cassina and Radi, 1996; Poderoso *et al.*, 1996; Takehara *et al.*, 1996).

Other critical enzymes inactivated by peroxynitrite in mitochondria include aconitase (Castro *et al.*, 1994; Hausladen and Fridovich, 1994; Kennedy *et al.*, 1997b) and creatine kinase (Konorev *et al.*, 1998; Stachowiak *et al.*, 1998), both linked to energy metabolism and ATP homeostasis. In addition, peroxynitrite inactivates Mn-SOD, which may play a critical role in propagating peroxynitrite-mediated mitochondrial damage. Since peroxynitrite interactions with mitochondrial electron transport chain components lead to enhanced O_2^- production (Radi *et al.*, 1994), the inactivation of Mn-SOD further contributes to raise intramitochondrial steady-state concentrations of O_2^- . Increased mitochondrial O_2^- contributes to mitochondrial and cell oxidative injury via combined mechanisms including reactions of reactive oxygen species with mitochondrial components, diffusion of its dismutation product hydrogen peroxide to the cytosol, and enhanced peroxynitrite formation in mitochondria.

The reaction of peroxynitrite with carbon dioxide would be particularly relevant in the mitochondrial matrix where CO_2 levels are high, due to its continuous production by the Krebs cycle. Glutathione consumption by peroxynitrite will lead to a decreased activity of mitochondrial glutathione peroxidase and therefore to an enhancement of H_2O_2 levels.

Peroxynitrite also influences mitochondrial calcium homeostasis, favoring calcium efflux from mitochondria (Gad-elha *et al.*, 1997; Packer and Murphy, 1994; Schweizer and Richter, 1996). The egress of calcium from mitochondria challenged by peroxynitrite is partly due to the inhibition of energy metabolism and also to the stimulation of the pyridine nucleotide-linked calcium release pathway. Finally, peroxynitrite increases mitochondrial membrane permeability by (a) opening of the permeability transition pore which depolarizes mitochondria and (b) a less specific mechanism involving membrane lipid and protein oxidation, leading to protein thiol cross-linking. Increased membrane permeability by peroxynitrite may lead to the release of components to the cytosol, including cytochrome *c*, that can participate in the mitochondrial signaling of apoptosis (Richter, 1998). Interestingly, excess $\cdot\text{NO}$ formation may lead to peroxynitrite-dependent cytochrome *c* nitration (Cassina *et al.*, 2000; Hortelano *et al.*, 1999) but the correlation between cytochrome *c* nitration, release, and apoptosis remains to be established.

Due to the multiplicity of mitochondrial targets and actions, the mitochondrial half-life of peroxynitrite is expected to be rather short (e.g., <5 ms) and therefore peroxynitrite is unable to diffuse significantly to extramitochondrial compartments.

LOW DENSITY LIPOPROTEIN OXIDATION

Peroxynitrite is a mediator of vascular injury in multiple forms of cardiovascular disease. First, peroxynitrite formation indirectly promotes atherogenesis by abrogating the physiological actions of $\cdot\text{NO}$, since peroxynitrite acts only as a comparatively weak stimulus for guanylate cyclase activity

in smooth muscle cells. Second, due to its potent oxidizing properties, peroxynitrite can participate in the oxidation of lipoproteins, whose modification is involved in the fatty streak production and subsequent plaque formation characteristic of the atherosclerotic lesion.

The low density lipoprotein (LDL) particle consists of an apolar core of cholesteryl esters and triglycerides, surrounded by a monolayer of phospholipids, unesterified cholesterol, lipophilic antioxidants (α -tocopherol, ubiquinol 10, β -carotene), and one molecule of apolipoprotein B-100. Cholesteryl esters are the most abundant lipid class found in LDL (Schuster *et al.*, 1995). Thus, both the lipid and protein components of LDL could potentially be oxidized and nitrated by peroxynitrite. Peroxynitrite oxidizes LDL, causing a rapid depletion of endogenous antioxidants such as α -tocopherol (Hogg *et al.*, 1993a) and carotenoids (Panassenko *et al.*, 2000; Pannala *et al.*, 1998). The simultaneous production of NO and $O_2^{\cdot-}$ by 1,3-morpholino-sydnonimine hydrochloride (SIN-1) has been shown to oxidize LDL to a potentially atherogenic form via formation of ONOO⁻ (Darley-Usmar *et al.*, 1992; Hogg *et al.*, 1993b; White *et al.*, 1994). Peroxynitrite converts the LDL to a form readily recognized by macrophage scavenger receptors (Graham *et al.*, 1993). More recently, it has been reported that exposure to peroxynitrite or SIN-1 resulted in time-dependent oxidation of both LDL lipids and protein (Thomas *et al.*, 1998).

Antibodies to nitrotyrosine show immunoreactivity in fatty streaks of coronary arteries of young autopsy subjects (Beckman *et al.*, 1994). In older patients, nitrotyrosine immunoreactivity is found in close association with foam cells and vascular endothelium, and in the neointima of advanced atherosclerotic lesions. In addition, measurements of 3-nitrotyrosine in LDL isolated from human atherosclerotic lesions show that there is a striking 90-fold increase compared with circulating LDL (Leeuwenburgh *et al.*, 1997).

Nitrotyrosine immunoreactivity may indicate peroxynitrite-dependent reactions during both early and chronic stages of atherosclerotic disease, which result in the formation of highly immunogenic and potentially proinflammatory protein oxidation products. However, it is important to note that myeloperoxidase may also play a role in nitrotyrosine formation during LDL modification because it can convert nitrite to a reactive intermediate that nitrates the aromatic ring of tyrosine (Eiserich *et al.*, 1996). Moreover, catalytically active myeloperoxidase is a component of human atherosclerotic tissue, where it colocalizes with foamy macrophages in the cellular-rich regions of lesions (Daugherty *et al.*, 1994). Oxidation products of the enzyme have been detected by immunohistochemistry in atherosclerotic vascular lesions, suggesting that myeloperoxidase promotes LDL oxidation *in vivo* (Hazell *et al.*, 1996; Podrez *et al.*, 1999). Thus, it is possible to envision a physiopathological scenario where endothelial and inflammatory cells contribute to LDL nitration via peroxynitrite-dependent and -independent mechanisms.

These observations raise the possibility that NO, by the formation of secondary nitrogen oxides (i.e., ONOO⁻, NO₂),

may promote atherogenesis, in contrast to its well-established direct antioxidant effects (Bolton *et al.*, 1994; Goss *et al.*, 1995; Hogg *et al.*, 1993c; Rubbo *et al.*, 1995; Rubbo and Radi, 2000).

Peroxynitrite Scavengers and Pharmacology

Pharmacological Approaches against Peroxynitrite-Mediated Toxicity

Peroxynitrite toxicity can be counteracted through several lines and direct scavenging is just one of them. In principle, any compound that inhibits NO production will yield an effective reduction of peroxynitrite formation, and the same principle is applicable to superoxide dismutation catalysis (Fig. 9). Therefore, NOS inhibitors and SOD mimics can be used to prevent peroxynitrite-mediated toxicity.

Once formed, peroxynitrite can be catalytically isomerized to nitrate or directly scavenged by sacrificial reductants; alternatively, the reactivity can be directed toward the oxidation of easily recoverable reductants such as glutathione, ascorbate, or uric acid.

Finally, if peroxynitrite damage is accomplished, some of its side effects may be reverted, such as reduction of radical intermediates and repair of oxidized moieties (Castro *et al.*, 1998) and potential reduction and elimination of nitrated groups (Kamisaki *et al.*, 1998; Grune *et al.*, 1998).

The design of peroxynitrite inactivators can involve more than one of the above-mentioned activities.

Peroxynitrite Scavengers

The scavenging of peroxynitrite in a biological milieu implies competition with other potential targets of oxidation.

Figure 9 Pharmacological interventions to prevent peroxynitrite-mediated injury. Peroxynitrite formation can be inhibited by dismutation of superoxide or inhibition of NOS, or it can be scavenged directly.

Success in that competition will depend on the concentration of targets, their reactivity, and properties of the medium such as pH.

It is clear that in many cases the reaction with CO_2 dictates a significant part of the fate of peroxynitrite. It is also clear that under conditions of oxidative stress the natural antioxidant systems (such as GSH) cannot directly cope with ONOOCO_2^- overproduction. Therefore, an efficient peroxynitrite scavenger would be able to divert ONOO^- oxidative potential toward “expendable” reductants and could inhibit ONOOCO_2^- formation, reactivity, or both.

Two different approaches have been devised to find a suitable decomposition catalyst: catalytic isomerization and catalytic reduction.

CATALYSIS OF ISOMERIZATION

Catalysis of peroxynitrite isomerization to nitrate represents an important strategy, given that relatively less toxic intermediates are formed during the catalytic process (Fig. 10, reaction *a*). Three iron porphyrins were reported to catalyze the isomerization to nitrate *in vitro*, with k_{cat} ranging from 10^5 to $10^6 \text{ M}^{-1} \text{ s}^{-1}$, and showed promising results in cell culture and animal models of inflammation (Misko *et al.*, 1998; Salvemini *et al.*, 1998). It is important to note, however, that a reactive intermediate is generated during the catalytic cycle, implying that these iron porphyrins redirect, more than abolish, peroxynitrite reactivity.

CATALYSTS OF REDUCTION

The rationale behind these scavengers is that they can be oxidized by peroxynitrite very rapidly and then be reduced back to the original compound by endogenous reductants in another fast reaction (Fig. 10, *b*). The selenium compound ebselen was the first proposed cyclic scavenger ($10^6 \text{ M}^{-1} \text{ s}^{-1}$) (Masumoto and Sies, 1996b) using glutathione as reductant.

More recently, SOD mimic manganese and iron porphyrins were found to act as catalysts of peroxynitrite reduction using ascorbate, glutathione, Trolox, or urate as reducing substrates (Ferrer-Sueta *et al.*, 1999; Lee *et al.*, 1997, 1998) with rate constants ranging from 10^6 to $10^7 \text{ M}^{-1} \text{ s}^{-1}$. However, the mechanism of this catalysis is not as simple as initially proposed; the metal (M) redox cycling between three 3+ and 4+ oxidation states should be expanded to include the 2+ state formed by reaction of the metal complexes with reductants. Studies are currently under way to understand the potential of these compounds as peroxynitrite scavengers.

OTHER SCAVENGERS

Hydroxamates Desferrioxamine has attracted attention as a potential scavenger although it does not react rapidly with peroxynitrite (Deliconstantinos and Villiotou, 1996; Denicola *et al.*, 1995; Lamarque and Whittle, 1995; Oury *et al.*, 1993; Radi *et al.*, 1991b). Desferrioxamine reaction with peroxynitrite leads to the formation of a desferrioxamine-derived nitroxide radical (Denicola *et al.*, 1995). This inhibition of peroxynitrite reactivity by desferrioxamine is independent of chelation of transition metals. Since there is no direct reaction between desferrioxamine and peroxynitrite, it is proposed to react with $\cdot\text{OH}$ but the mechanism of inhibition remains to be established (Beckman *et al.*, 1990; Radi *et al.*, 1991b; Alvarez *et al.*, 1995; Denicola *et al.*, 1995).

Guanidine Derivatives Guanidine derivatives integrate two functions; they serve as inhibitors of iNOS, thus inhibiting $\cdot\text{NO}$ overproduction under conditions of inflammation. Additionally, a reactive group, such as a thiol (e.g., mercaptoethyl guanidine) can be attached to the guanidine moiety to provide some direct scavenging of peroxynitrite

Figure 10 Catalysis of isomerization and reduction of peroxynitrite. (*a*) Fe^{IV} porphyrins can catalyze the isomerization of peroxynitrite. (*b*) The one-electron redox-cycling of Mn and Fe porphyrins has been shown to catalyze the reduction of peroxynitrite. (*c*) Metal porphyrins can also catalyze the autooxidation of glutathione and ascorbate.

(Brahm *et al.*, 1998; Cuzzocrea *et al.*, 1998; Lohinai *et al.*, 1998; Panas *et al.*, 1998; Szabo, 1998; Szabo *et al.*, 1997a; Zingarelli *et al.*, 1997, 1998) and proved to be efficient in different models of peroxynitrite-mediated injury.

Conclusions

Peroxynitrite, the reaction product of NO and O_2^- , is a strong oxidizing biomolecule. Both ONOO⁻ and ONOOH participate in a variety of reactions including one- and two-electron oxidations, nitrations, and to a lesser extent nitrosation. Biologically, direct reactions of peroxynitrite with biomolecules predominate over homolysis of ONOOH. Preferential reactions *in vivo* include those with CO₂, metal centers, and thiols. Formation of ONOOCO₂⁻ and peroxynitrite-transition metal adducts redirects peroxynitrite reactivity and promote nitrations (e.g., tyrosine nitration). Glutathione plays a central role in inhibiting oxidation processes mediated by peroxynitrite. The biological half-life of peroxynitrite is short, typically less than 20 ms, due to target molecule reactions. However, this time is long enough for peroxynitrite to travel one or two cell diameters and exert toxic effects in target cells or extracellular milieu. In addition to its direct cytotoxic effects by interactions with biomolecules and subcellular structures, the role and mechanisms of peroxynitrite modulation of signal transduction pathways and signaling of cell death remain to be elucidated. Pharmacological strategies against peroxynitrite toxicity are being developed and will help both to unravel the contribution of peroxynitrite to oxidant-mediated pathologies and to neutralize its deleterious effects.

THE MAIN GOAL OF THIS CHAPTER IS TO COMPARE AND CONTRAST THE BIOLOGICAL REACTIVITY OF NITRIC OXIDE AND PEROXYNITRITE WITH PROTEINS. NITRIC OXIDE AND PEROXYNITRITE REACT SELECTIVELY WITH DIFFERENT PROTEINS, CAUSING LOCAL OR EVEN LONG-RANGE STRUCTURAL ALTERATIONS THAT MODIFY PROTEIN FUNCTION. THIS CHAPTER REVIEWS FACTORS THAT DETERMINE THE GENERAL BIOLOGICAL REACTIVITY OF NITRIC OXIDE AND PEROXYNITRITE WITH BIOMOLECULES AND THE FACTORS THAT DETERMINE THE REACTIVITY WITH PROTEINS.

Introduction

The proteins that are selectively modified by nitric oxide fall into four major categories: (1) heme and non-heme iron-containing proteins (Murad, 1996; Moore and Gibson, 1986; Craven and DeRubertis, 1978; Lancaster *et al.*, 1992; Ribeiro *et al.*, 1993; Gardner *et al.*, 1998; Hausladen *et al.*, 1998; Tsubaki *et al.*, 1987; Khatsenko *et al.*, 1993), (2) proteins with iron-sulfur clusters (Kennedy *et al.*, 1997; Cassina and Radi, 1996; Clementi *et al.*, 1998; Bouton *et al.*, 1986; Pantopoulos *et al.*, 1994), (3) proteins with liable cysteine residues (Simon *et al.*, Molina y Vedis *et al.*, 1992; Lander *et al.*, 1996; Xu *et al.*, 1998; Lipton *et al.*, 1993; Gow and Stamler, 1998; Kim *et al.*, 1997), and (4) proteins containing tyrosine residues that undergo one-electron oxidation to form tyrosyl radical (Gunthers *et al.*, 1997; Goodwin *et al.*, 1998; Guittet *et al.*, 1998). Examples for the first category include guanylate cyclase, hemoglobin, cytochrome

P-450, insect salivary heme protein, and bacterial flavo-hemoglobin (Murad, 1996; Moore and Gibson, 1976; Craven and DeRubertis, 1978; Lancaster *et al.*, 1992; Ribeiro *et al.*, 1993; Gardner *et al.*, 1998; Hausladen *et al.*, 1998; Tsubaki *et al.*, 1987; Khatsenko *et al.*, 1993). Among proteins in the second group are aconitase, mitochondrial electron transport chain complexes, and the iron regulatory element, all of which represent iron-sulfur targets for nitric oxide (Kennedy *et al.*, 1997; Cassina and Radi, 1996; Clementi *et al.*, 1998; Bouton *et al.*, 1996; Pantopoulos *et al.*, 1994). In the third group, glyceraldehyde-3-phosphate dehydrogenase (GAPDH), ryodine receptor, p21ras hemoglobin, and caspase 3 are all modified by S-nitrosylation of cysteine residues (Table 1). Prostaglandin H synthase-2, prostaglandin endoperoxidase synthase, and ribonucleotide reductase are examples of proteins in which nitric oxide has been shown to react with the tyrosyl radical (Gunthers *et al.*, 1997; Goodwin *et al.*, 1998; Guittet *et al.*, 1998).

Table 1 Proteins Modified by S-Nitrosylation

Protein	Function	Model	S-nitrosylated function	Site of S-nitrosylation
Glyceraldehyde-3-phosphate dehydrogenase	Glycolysis	Rat liver of <i>C. parvum</i> model of chronic hepatic inflammation (Molina y Vedia <i>et al.</i> , 1992)	Inhibits enzymatic activity and increases endogenous ADP-ribosylation	Possibly C ₁₄₀ in the active site
p21ras	Signal transduction	Cells exposed to nitric oxide donors (Lander <i>et al.</i> , 1996)	Activation of MAP kinase, signal transduction	C ₁₁₈
Ryanodine receptor	Cardiac calcium regulation	Canine hearts (Xu <i>et al.</i> , 1998)	Reversible channel activation	Multiple residues
NMDA receptor	Synaptic transmission, Ca ²⁺ homeostasis	Neuronal cell models exposed to nitric oxide donors (Lipton <i>et al.</i> , 1993)	Increases Ca ²⁺ efflux and neurotoxicity	nd ^a
Hemoglobin	Oxygen transport	Rat blood (Gow and Stamler, 1998)	Control of blood pressure	C ₉₃
Caspase-3	Cysteine protease, execution of apoptosis	Cells exposed to nitric oxide donors (Kim <i>et al.</i> , 1997)	Inhibits activity	nd

^and, not determined.

Two amino acids have been shown to be the major targets for peroxynitrite in proteins, tyrosine and cysteine (Ischiropoulos, 1998; Radi *et al.*, 1991). The reaction with tyrosine results in the formation of 3-nitrotyrosine and the reaction with cysteine generates oxidized forms of cysteine, and to a lesser extent, S-nitrosocysteine (Ischiropoulos, 1998; Radi *et al.*, 1991; Vliet *et al.*, 1998; Balazy *et al.*, 1998). Peroxynitrite also selectively reacts with zinc–sulfur and iron–sulfur centers of proteins (Crow *et al.*, 1995; Keyer and Imlay, 1997). *In vivo*, a number of proteins have been found to be modified by nitration: Mn superoxide dismutase, prostacyclin synthase, Ca²⁺-ATPase, tyrosine hydroxylase, and the plasma proteins, ceruloplasmin, transferrin, α1 antichymotrypsin, α1-protease inhibitor, and fibrinogen (Table II, MacMillan-Crow *et al.*, 1996; Yamakura *et al.*, 1998; Zhou *et al.*, 1998; Viner *et al.*, 1996; Klebl *et al.*, 1998; Ara *et al.*, 1998). Peroxynitrite has been implicated as the proximal nitrating species for the *in vivo* nitration of prostacyclin synthase and tyrosine hydroxylase (Zhou *et al.*, 1998; Ara *et al.*, 1998).

Currently, there are no examples of specific proteins modified by S-nitrosylation of cysteine(s) via the reaction with peroxynitrite. Although both nitric oxide and peroxynitrite have been also shown to react with and modify tryptophan residues, no specific proteins and targets have been identified *in vivo* (Alvarez *et al.*, 1996; Zhang *et al.*, 1996).

A number of specific proteins are modified by either nitric oxide or peroxynitrite, and the factors which determine this selectivity are currently being investigated. Based on this limited new information, as well as on the known biochem-

Table II Nitrated Proteins in Human Disorders and Animal or Cellular Models of Disease^a

Protein	Function	Human pathology/model	Effect of nitration	Site of nitration
Mn-Superoxide dismutase	Decrease superoxide steady-state levels	Rejected human renal allografts (MacMillan-Crow <i>et al.</i> , 1996)	Loss of function	Residue Y34 (Yamakura <i>et al.</i> , 1998)
Prostacyclin synthase	Prostacyclin synthesis	IL-1β-treated mesangial cells (Zhou <i>et al.</i> , 1998)	Loss of function	nd ^b
Sarcoplasmic reticulum Ca ²⁺ -ATPase	Calcium and energy homeostasis	Aged rat skeletal muscle (Viner <i>et al.</i> , 1996), low-frequency stimulation of muscle (Klebl <i>et al.</i> , 1998)	Loss of function	nd
Tyrosine hydroxylase	Rate limiting step in catecholamine synthesis	MPTP mouse model of Parkinson's disease (Ara <i>et al.</i> , 1998)	Loss of function	One residue per molecule

^aEvidence that the proximal species for nitration is peroxynitrite or ONO(O)CO₂⁻ is provided for prostacyclin synthase and tyrosine hydroxylase. Prostacyclin synthase was nitrated only upon exposure to nitric oxide and superoxide donors but not to nitric oxide donors without a source of superoxide (Zhou *et al.*, 1998). IL-1β was also shown to nitrate the cytoskeleton of smooth muscle cells but no specific proteins have been determined (Boota *et al.*, 1996). Tyrosine hydroxylase was not nitrated in mice overexpressing Cu,Zn-superoxide dismutase in their brains (Ara *et al.*, 1998). These mice as well as NOS1 knock-out mice are resistant to MPTP neurotoxicity (Przedborski *et al.*, 1992, 1996).

^bnd, not determined.

ical properties of nitric oxide and peroxynitrite, we will outline and discuss factors that may play a critical role in the selective biological reactivity of nitric oxide and peroxynitrite with proteins. These factors include the chemical nature of the reactants, the rate constant and concentration of the reactants, compartmentalization, specific pathways of removal or scavenging, and biophysical properties of the target protein.

Chemical Nature of the Reactant

Both nitric oxide and peroxynitrite are simple molecules. However, despite their simplicity in structure, the diversity of the biological reactivity of these two molecules is daunting—covering the range from physical chemistry to human physiology and pathology in nearly all major organs. In part, their biological reactivity is determined by their chemical and physical properties, nitric oxide being a free radical and peroxynitrite an oxidant. The free radical nature of nitric oxide is important for its interaction with heme iron-containing proteins, iron–sulfur clusters, and with other radical species. In general, nitric oxide is a mild oxidant and reductant, therefore the oxidoreductive chemistry of nitric oxide may be limited to specific environments and with specific biological targets. The biophysical properties of nitric oxide are similar to oxygen (Meyer *et al.*, 1990). Both are hydrophobic, gaseous molecules with similar solubility in biological fluids and ability to establish diffusion gradients. Both oxygen and nitric oxide are capable of undergoing reactions that will cause stress and in the extreme, a pathogenic outcome. Oxygen toxicity has been studied extensively over the past 40 years. The partial reduction of oxygen by one electron to form superoxide and/or by two electrons to form hydrogen peroxide is the biochemical reason for the toxicity of oxygen (Fridovich, 1997; Freeman and Crapo, 1982). Despite the presence of specific enzymatic antioxidant defenses, superoxide and hydrogen peroxide are capable of causing tissue pathology. Similarly, nitric oxide can undergo reactions with oxygen to produce nitrogen species with higher oxidation potential, or with superoxide to generate peroxynitrite. The reactive nitrogen species and peroxynitrite are capable of reacting with proteins, lipids, and DNA to produce a pathogenic outcome (Beckman and Koppenol, 1996).

In contrast to nitric oxide, peroxynitrite is not a free radical but an oxidant and nitrating agent. Peroxynitrite has been studied in the context of a mineral salt found on the planet Mars, as well as in the pathophysiology of most neurological, pulmonary, and circulatory disorders. The physical properties of peroxynitrite (Beckman and Koppenol, 1996; Squadrito and Pryor, 1998) allow it to transverse biological membranes and to be surprisingly selective in reacting with biological targets. Contrary to previous assumptions that biological membranes may act as a formidable barrier to limit the reactivity of peroxynitrite, two recent studies clearly establish that peroxynitrite is capable of diffusing through cell

membranes (Marla *et al.*, 1997; Denicola *et al.*, 1998). Possibly the most important reaction of peroxynitrite in biology is the reaction with carbon dioxide (Lymar *et al.*, 1996; Uppu *et al.*, 1996; Denicola *et al.*, 1996; Gow *et al.*, 1996a). The reaction of peroxynitrite with CO₂ leads to the formation of a nitrocarbonate (ONO(O)CO₂[−]) intermediate. This intermediate is a less potent one- or two-electron oxidant compared to peroxynitrite (Denicola *et al.*, 1996). However, the ONO(O)CO₂[−] adduct is an efficient and potent nitrating agent (Denicola *et al.*, 1996; Gow *et al.*, 1996a). Recent data indicate that the ONO(O)O₂[−] adduct is also capable of nitrosylating biomolecules such as thiols and uric acid (possible biological targets modified by nitration are shown in Fig. 1) (Skinner *et al.*, 1998; White *et al.*, 1999; Koppenol, 1998; Uppu *et al.*, 1998). Nitrosated adducts of reduced thiols and uric acid as well as mononitrated or dinitrated adducts of glycerol are biologically active nitric oxide donors (Vliet *et al.*, 1998; Balazy *et al.*, 1998; Skinner *et al.*, 1998; White *et al.*, 1999). These adducts provide a mechanism for the formation of endogenous vasodilators and may play a role in the cellular adaptation to stress. The reaction of peroxynitrite with CO₂ is an emerging area of research that has important ramifications in determining the outcome from the biological reactivity of peroxynitrite.

Aspects of the chemical reactivity of peroxynitrite and of ONO(O)CO₂[−], such as the formation of radical species (·OH and ·NO₂) and the formation of oxidized and nitrosated phenolics, remain controversial (Koppenol, 1998; Uppu *et al.*, 1998). In reviewing the literature, however, it appears that much of this controversy results from a remarkably simple variable: the method used for the synthesis of peroxynitrite. Peroxynitrite can be synthesized by a variety of methods, each producing solutions with different contaminants and possibly different isomers of peroxynitrite with different reactivity. Moreover, methodologies used for *in situ* synthesis are also plagued by problems that will be discussed below.

Rate of Reaction with Biological Targets

The second factor that may determine the reactivity of nitric oxide and peroxynitrite is the rate of reaction with the biological targets. The rate is a function of the rate constant and the concentration of the reactants. Kinetically favored and thermodynamically feasible reactions need to be consid-

Figure 1 Possible biological targets modified by nitration.

ered first. The reactions of nitric oxide with heme iron, non-heme iron, iron-sulfur clusters, and tyrosyl radical are kinetically and thermodynamically favored (Koppenol, 1998). In contrast, the reaction of nitric oxide with cysteine is relatively slow and is not thermodynamically favored in the absence of an electron acceptor (Gow *et al.*, 1997). However, since the cysteine concentration in proteins and glutathione is higher than the concentration of all other putative targets, the overall rate of this reaction may be high enough to compete with the other pathways.

There is clear evidence for the formation of *S*-nitrosothiols *in vivo*; however, the nature of the nitrosating agent(s) remains unclear (Simon *et al.*, 1996; Molina y Vedra *et al.*, 1992; Lander *et al.*, 1996; Xu *et al.*, 1998; Lipton *et al.*, 1993; Gow and Stamler, 1998; Kim *et al.*, 1997). Formation of *S*-nitrosothiols may proceed via a number of reactive pathways, catalyzed by metal, by the oxidation of thiol to thiyl radical followed by coupling of the radical with nitric oxide, or via the formation of a radical intermediate which donates the free electron to an electron acceptor (Gow *et al.*, 1997; Boese *et al.*, 1995). Another alternative is the reaction of nitric oxide with peroxynitrite to form dinitrogen trioxide (Wink *et al.*, 1997; Mayer *et al.*, 1998). However, the reaction between nitric oxide and peroxynitrite is not kinetically favored since the concentration of both reactants is low. The formation of higher nitrogen oxides by the trimolecular reaction of nitric oxide with oxygen generates nitrosating species. However, the reaction of nitric oxide with oxygen is relatively slow and hence it is unlikely to compete successfully with any of the other nitric oxide targets except in special environments. The reaction of nitric oxide with oxygen may take place in hydrophobic environments such as cell membranes where the concentration of both reactants is higher than in the cytosol or in the extracellular environment (Liu *et al.*, 1998). A six- to 10-fold increase in the concentration of nitric oxide and oxygen in the phospholipid bilayer may promote the formation of nitrogen oxides. Moreover, in the membranes, alternative targets are either absent or present in concentrations lower than that of O₂, favoring the reaction between nitric oxide and oxygen (Liu *et al.*, 1998). The nitrogen oxides are reactive and hydrate easily to give nitrite and nitrate, limiting their biological function to the membrane bilayer where they may be important for the formation of nitrosated and nitrated lipid adducts (O'Donnell *et al.*, 1998).

The predominant protein modification by peroxynitrite, even in the presence of alternative pathways such as reduce thiols, is with tyrosine residues to form 3-nitrotyrosine. This is a paradox since the apparent second-order rate constant of the reaction of peroxynitrite with the free amino acid is zero (Alvarez *et al.*, 1998). The same study determined the second-order rate constants of peroxynitrite reacting with each free amino acid. Cysteine had the highest second-order rate constant, suggesting that it should be the primary target reacting with peroxynitrite. Indeed, rendering the single cysteine residue of BSA inactive by derivatization prior to the reaction with peroxynitrite increased the yield of tyrosine

nitration (Alvarez *et al.*, 1998). That nitration of protein tyrosine residues takes place, even in the presence of reduce thiols and other peroxynitrite scavengers (Gow *et al.*, 1996; Alvarez *et al.*, 1998), indicates that simple rate constants are not the only factors determining the biological reactivity of nitric oxide and peroxynitrite. Their modest rate of reaction with different targets extends their biological half-life. The consequence of extending the biological half-life of a reactive species is to increase its diffusion distance, which then amplifies the sphere of biological influence and permits reactions with selective targets. For nitric oxide, diffusion is not a problem, and it may establish large diffusion gradients as long as the various isoforms of nitric oxide synthases are continuously generating nitric oxide. Under this situation the diffusion distance is then limited by reactivity with targets, specific removal, and scavenging. The selectivity of reactivity determines which targets will be modified before the diffusion gradient is decimated.

A final point regarding studies of reactivity of nitric oxide and peroxynitrite pertains to using *in vitro* generating systems of nitric oxide and superoxide. These *in vitro* models have provided important information on the oxidizing, nitrosating and nitrative reactivity of nitric oxide and peroxynitrite (Wink *et al.*, 1997; Mayer *et al.*, 1998; Pfeiffer and Mayer, 1998). They were also useful in providing evidence for secondary reactions between nitric oxide and peroxynitrite (Wink *et al.*, 1997; Mayer *et al.*, 1998). However, much of the *in vitro* reactivity does not simulate *in vivo* conditions. For example, these systems typically use a single target to determine outcome, whereas in biology many targets will be present. Some models have been performed in the absence of CO₂; these play a major role in the reactivity of peroxynitrite (Wink *et al.*, 1997). Exposing targets, cells, or tissues to exogenous nitric oxide and/or peroxynitrite may not always produce the same outcome as with the endogenous generation of these species. A good example is our own experience with the detection of nitrated proteins in plasma after exposure to nitric oxide and superoxide as compared with the endogenous generation of nitrating agents in acute respiratory distress syndrome (ARDS). The major protein that is nitrated upon exposure of human plasma to nitrating agent is albumin. However, albumin was not one of the five plasma proteins that have been identified as nitrated in ARDS patients. At first glance it is surprising that a protein that comprises over 50% of the total protein in plasma and contains 18 tyrosine residues is not nitrated *in vivo*. Another surprising finding is that the yield and efficiency of nitration of the free amino acid tyrosine are significantly lower (no apparent second-order rate constant) than the yield of nitration of selective tyrosine residues in proteins (MacMillan *et al.*, 1996; Yamakura *et al.*, 1998; Zhou *et al.*, 1998; Viner *et al.*, 1996; Klebl *et al.*, 1998; Ara *et al.*, 1998). The local environment of tyrosine residues in proteins and the protein structure appear to facilitate nitration of specific tyrosine residues in proteins (discussed below). This is consistent with observations that stimulated neutrophils supplemented with nitrite failed to nitrate phagocytized small-aromatic sub-

strates (Jiang and Hurst, 1997) but effectively nitrated proteins in phagocytized bacteria (Evans *et al.*, 1996). Although test-tube experiments may be fundamental in understanding basic aspects of the chemical reactivity of nitric oxide and peroxynitrite, we should also consider the findings in biological models and human disease before drawing conclusions regarding the biological reactivity of nitric oxide and peroxynitrite.

Cellular Compartments and Biological Reactivity

The importance of magnitude of the sphere of biological influence is diminished when one considers issues of microenvironments and compartmentalization. Cellular microenvironments such as the membrane, mitochondria, and sites of superoxide generation allow for the formation of higher nitrogen oxides and peroxynitrite. We have reasoned that the biological reactivity of peroxynitrite is closely associated with the sites of superoxide formation. The superoxide dismutases maintain a low steady-state level of superoxide and thus prevent reactions between superoxide and iron-sulfur proteins or nitric oxide (Fridovich, 1997). However, in local environments where the superoxide dismutase is not efficient in removing superoxide, and under conditions where higher levels of superoxide are generated, peroxynitrite will be formed. This may be the case with the selective destruction of dopaminergic neurons in the MPTP model of Parkinson's disease (Ara *et al.*, 1998; Przedborski *et al.*, 1992, 1996). These neurons produce higher than normal superoxide during the metabolism of MPTP and thus are susceptible to peroxynitrite. Dopaminergic neurons in mice overexpressing Cu, Zn superoxide dismutase, or in mice without neuronal NOS1 (NOS1 knock-out), are protected from MPTP neurotoxicity (Przedborski *et al.*, 1992, 1996). The MPTP-induced nitration of a specific protein, tyrosine hydroxylase, is prevented in the mice overexpressing Cu,Zn-superoxide, providing evidence for the role of superoxide in nitration of proteins *in vivo* (Ara *et al.*, 1998).

Specific Pathways of Removal and Scavenging Pathways

The first line of cellular defense from reactive species is avoiding their formation. Maintaining coupling of electron transfer in the mitochondrial respiratory chain, within cytosolic proteins that catalyze different oxidations such as the cytochrome P-450 and monooxygenases, as well as nitric oxide synthases, prevents electron transfer to oxygen. The second line of defense is the presence of enzymatic defenses against the reactive species. Superoxide dismutases, glutathione peroxidase, and catalase remove superoxide and hydrogen peroxide. A mammalian equivalent to the recently described bacterial NO reductases has not been described. This flavohemoprotein is capable of specifically removing nitric oxide in bacteria (Gardner *et al.*, 1998; Hausladen *et*

al., 1998). The selenium-dependent glutathione peroxidase and possibly selenoprotein P may serve as peroxynitrite reductases in mammalian cells (Arteel *et al.*, 1999; Burk and Hill, 1999). The third line of defense is the repair mechanisms. Oxidized protein, and, to a certain extent, nitrated proteins, are proteolytically degraded and removed (Davies, 1987; Gow *et al.*, 1996b). Recent evidence also indicates that a nonproteolytic pathway can repair nitrated proteins (Gow *et al.*, 1996b; Kamisaki *et al.*, 1998). This activity is present in most rodent tissues and is induced by endotoxin or by nitrative stress (Kamisaki *et al.*, 1998). A similar activity may exist in human tissues. A decline in the lung biopsy levels of 3-nitrotyrosine has been reported in an infant who survived septic lung injury (Haddad *et al.*, 1994). The overall magnitude of plasma protein 3-nitrotyrosine declined in infants with improved oxygenation and clinical outcome after treatment to alleviate symptoms of bronchopulmonary dysplasia (Banks *et al.*, 1999).

Selection of Preferential Target

The following question remains: how do free radicals, oxidants, and nitrating agents select their biological targets? A number of the factors listed previously may determine the selective modification of biological targets. To answer this question we must also consider the factors that predispose a target to modification. The information appears to be embedded in the structure and local environment afforded by specific amino acids in the protein. For example, soluble guanylate cyclase does not bind oxygen, but it will bind nitric oxide and, to a lesser extent, carbon monoxide (Stone and Marletta, 1994). The coordination of the ligand nitric oxide in the heme iron active site is essential for the functional activation of the protein. Another example is the S-nitrosylation of cysteine 93 in hemoglobin. During the transition of hemoglobin from T to R state, the cysteine residue is exposed to solvent and is S-nitrosylated (Gow and Stamler, 1998). Nitration of tyrosine residues in a protein is also a selective process. Experimental evidence established that only a few proteins are nitrated *in vivo* (Ara *et al.*, 1998). Recent work from our laboratory determined the sites of tyrosine nitration on different proteins. Several factors appear to be critical for determining the selectivity of nitration: (1) location of the tyrosine on a loop but not in α -helical or β -sheet structure (usually near turn-inducing residues such as glycine and proline), (2) absence of nearby cysteine or disulfide bridge, (3) paucity of positive charges, (4) exposure to the surface, and (5) most importantly the presence of a nearby negative charges.

The selective modification of cysteine and tyrosine residues may have a profound effect in the biological function (Tables I and II). S-nitrosylation of cysteine residues is a reversible process and thus it does not have a long-lasting effect on biological function. Similarly, the repair of tyrosine nitration and proteolytic degradation may prevent the long-term effects on protein function induced by nitration. The

failure to repair modified proteins is likely to result in accelerated protein turnover and other disturbances in cell function that will lead to the development of a pathogenic phenotype.

Summary

Despite differences in structure and chemical reactivity, nitric oxide and peroxynitrite may share similar biological reactivity. Both species modify critical residues in proteins, and nitric oxide induces S-nitrosylation of cysteine residues and peroxynitrite, most likely via its reaction with CO₂, tyrosine nitration. In most cases, modification of a single residue per protein molecule is sufficient to induce a loss or gain of function (Tables I and II). To maintain normal physiological function, the protein modification is reversible or the modified protein is repaired. Failure to repair the modified proteins may result in a pathological outcome.

Structural Variations to Accommodate Functional Themes of the Isoforms of NO Synthases

Bettie Sue Masters

*Department of Biochemistry
The University of Texas Health Science Center
San Antonio, Texas*

NITRIC OXIDE SYNTHASES ARE RESPONSIBLE FOR THE ENZYMATIC FORMATION OF NITRIC OXIDE ($\text{NO}\cdot$), THE DIATOMIC GAS RESPONSIBLE FOR A VARIETY OF CELLULAR SIGNALING EVENTS IN NEURONAL, SKELETAL MUSCLE, AND ENDOTHELIAL CELLS AND FOR THE PRODUCTION OF REACTIVE OXYGEN SPECIES RESPONSIBLE FOR DESTRUCTION OF MICROORGANISMS AND TUMOR CELLS BY PHAGOCYTIC CELLS. THE FOLLOWING DESCRIBES THE PRESENT STATE OF KNOWLEDGE OF THREE GENETICALLY DETERMINED ISOFORMS OF NITRIC OXIDE SYNTHASE. THESE ENZYMES SHARE A STRONG SIMILARITY WITH RESPECT TO PROSTHETIC GROUP COMPOSITION AND BASIC CHEMICAL MECHANISMS, BUT THEY DIFFER MARKEDLY IN AMINO ACID SEQUENCE, MOLECULAR MASS, AND REGULATORY CONTROL. ALTHOUGH NO REVIEW CAN BE TOTALLY COMPREHENSIVE, IT WILL BE THE GOAL OF THIS CHAPTER TO DESCRIBE THE UNIQUE FUNCTIONS OF THE NITRIC OXIDE SYNTHASES AS DETERMINED BY THEIR STRUCTURAL PROPERTIES WITH REFERENCE TO THEIR LOCATIONS WITHIN SPECIFIC CELLS. WHILE THERE IS MUCH TO BE LEARNED OF THE COMPLETE STRUCTURES OF THESE ISOFORMS, IT IS POSSIBLE TO REVIEW THE PERTINENT LITERATURE FOR INFORMATION LEADING TO THE UNDERSTANDING OF THE REGULATION OF FORMATION OF $\text{NO}\cdot$ IN VARIOUS ORGANS AND CELL TYPES. IT IS HOPED THAT BY DETERMINING THREE-DIMENSIONAL STRUCTURES, INVESTIGATORS WILL GAIN INFORMATION REGARDING POSSIBLE MECHANISMS FOR DIFFERENTIAL REGULATION OF THE NITRIC OXIDE SYNTHASES WITHIN THE CELLULAR MILIEU AND INSIGHTS INTO THE DESIGN OF POSSIBLE THERAPEUTIC AGENTS, WHICH CAN SPECIFICALLY INHIBIT ONE ISOFORM AS OPPOSED TO THE OTHER.

Nitric Oxide Synthases: Historical Introduction and Functional Aspects

Nitric oxide ($\text{NO}\cdot$)-producing enzymes have been logically named nitric oxide synthases (NOS), but the derivation of the nitrogen of $\text{NO}\cdot$ from the guanidino nitrogen of L-arginine, one of the amino acid building blocks of cellular

proteins, was unexpected. Before any of the enzymes were isolated and purified, first from rat brain cerebella (Bredt and Snyder, 1990), the activities were often referred to as guanylate cyclase-activating enzymes. In fact, the initial observations by Murad and colleagues (Arnold *et al.*, 1977) led to the proposal that $\text{NO}\cdot$, generated by nitroglycerin and other nitric oxide-producing compounds, acted on guanylate

cyclase to cause increases in the tissue levels of cGMP. This finding laid the chemical foundation for the possible function of NO• as a mediator in biological processes.

Early studies by Furchgott and Zawadski (1980), showing that endothelial cells serve an obligatory role in acetylcholine-mediated relaxation of arterial smooth muscle, were seminal in further examination of the factors involved in signaling vasorelaxation. When Furchgott (1988), Ignarro *et al.* (1987), and Palmer *et al.* (1987) subsequently independently reported that endothelium-derived relaxing factor (EDRF) was NO•, a new field exploded onto the scientific scene. These exciting discoveries formed the basis for the awarding of the Nobel Prize in Medicine or Physiology to Robert A. Furchgott, Louis J. Ignarro, and Ferid Murad in 1998. The studies of Furchgott (1988) and Moncada's group (Palmer *et al.*, 1987) produced strong evidence of a role for NO• in blood flow regulation, and experiments from Tannenbaum's laboratory in rodents and humans (Green *et al.*, 1981a,b; Leaf *et al.*, 1990) had shown that L-arginine was the precursor of nitrate (NO₃⁻ and nitrite (NO₂⁻). The stage was now set to search for the enzymes that produce NO• in various tissues.

After Garthwaite *et al.* (1988) showed that NO• could act as an intracellular messenger in the brain, Bredt and Snyder reported (1990) the isolation and purification of neuronal nitric oxide synthase (nNOS). In these studies they showed the requirement for Ca²⁺/calmodulin (Ca²⁺/CaM) for the elicitation of L-arginine to L-citrulline conversion. Immediately thereafter, Snyder and colleagues (Bredt *et al.*, 1991) and Mayer *et al.* (1991) determined that nNOS contains both flavin adenine dinucleotide (FAD) and flavin mononucleotide (FMN) in 1:1 stoichiometry, and Bredt *et al.* (1991) reported that the amino acid sequence of its 641-residue C terminus was highly homologous to NADPH-cytochrome P-450 reductase. These findings were to be portentous of mechanistic aspects of the NOS isoforms being similar to the interaction of NADPH-cytochrome P-450 reductase with a large number of heme-containing cytochromes P-450 in the endoplasmic reticulum of various mammalian organs. The laboratories of Marletta (Hevel *et al.*, 1991) and Nathan and colleagues (Stuehr *et al.*, 1991) also reported the flavo-protein nature of inducible NOS (iNOS), having already demonstrated that iNOS from mouse macrophages absolutely requires tetrahydrobiopterin [(1'R,2'S,6R)-5,6,7,8-tetrahydrobiopterin; H₄B] for activity (Tayeh and Marletta, 1989; Kwon *et al.*, 1989); a similar requirement for H₄B in nNOS was demonstrated by Mayer *et al.* (1990) and Murad and co-workers (Schmidt *et al.*, 1992). These discoveries led to some complacency in the field that all prosthetic groups required for enzymatic activity had been identified. This was not to be the case as, in 1992, the simultaneous discovery of a single iron protoporphyrin IX (heme) per monomer was made by four independent laboratories (McMillan *et al.*, 1992; White and Marletta, 1992; Stuehr and Ikeda-Saito, 1992; Klatt *et al.*, 1992), when spectral data showed a reduced, CO difference spectrum at approximately 450 nm, suggesting a cysteine thiolate-liganded heme.

Until this time, all experiments on purified nitric oxide synthases depended on purification of the enzymes from natural sources, that is, cerebellum for nNOS (Mayer *et al.*, 1991; White and Marletta, 1992) or murine macrophages for iNOS (White and Marletta, 1992; Stuehr and Ikeda-Saito, 1992), or an alternative source being the human kidney 293 cells into which the cDNA for rat neuronal NOS had been transfected (Bredt *et al.*, 1991; McMillan *et al.*, 1992; Stuehr and Ikeda-Saito, 1992). Later, Richards and Marletta (1994), using a baculovirus expression system, expressed the nNOS holoenzyme, and the Masters' laboratory (McMillan and Masters, 1995), using an *Escherichia coli* expression system to express the heme domain of nNOS, employed site-directed mutagenesis to identify the proximal heme ligand as cysteine-415, as predicted by McMillan *et al.* (1992) from sequence alignments of the isoforms. The introduction, soon thereafter, of heterologous expression systems by Roman *et al.* (1995) and Gerber and Ortiz de Montellano (1995) for the expression of nNOS holoenzyme in *E. coli* revolutionized the ability to obtain large-scale amounts of material with a high percentage of heme incorporation required for biophysical studies, such as electron paramagnetic resonance spectroscopy and crystallography.

In light of the sequence homology of the C-terminal half of nNOS to NADPH-cytochrome P-450 reductase (Bredt *et al.*, 1991), the discovery of the cysteine thiolate-liganded heme prosthetic group induced much speculation regarding the mechanism of monooxygenation catalyzed by the NOS isoforms (Marletta, 1993; Klatt *et al.*, 1993). Heme iron has been shown to be the site of oxygen binding in the cytochrome P-450-mediated systems, but it had been assumed that in the NOS isoforms, on the identification of the requirement for H₄B for catalysis (Tayeh and Marletta, 1989; Kwon *et al.*, 1989; Mayer *et al.*, 1990, 1991; Schmidt *et al.*, 1992), pterin would be the oxygen-activating prosthetic group. In addition, the enigma of the role of H₄B involvement in NOS function continues, having been confounded as a result of the finding of heme as a prosthetic group in the NOS isoforms. Possible roles for H₄B in NOS catalysis will be discussed in detail later in this review. As if the aforementioned prosthetic groups were not enough, during the X-ray crystallographic studies reported by Raman *et al.* (1998) on the bovine eNOS heme domain dimer, a metal tetrathiolate center containing zinc (ZnS₄) was found. Crystal structures of both human eNOS and human iNOS by Fischmann *et al.* (1999) and of human iNOS by Li *et al.* (1999) in Poulos' laboratory have also been shown to contain ZnS₄ centers. More recently, the Tainer, Getzoff, and Stuehr laboratories (Crane *et al.*, 1999) have confirmed the presence of zinc in crystal structures of murine iNOS but also reported the solution of a Zn-free structure. Subsequently, all three NOS isoforms have been found to contain zinc, based on biochemical studies of nNOS and eNOS by Miller *et al.* (1999) in Masters' laboratory and by the laboratories of Ortiz de Montellano (Rodríguez-Crespo *et al.*, 1999) and Mayer (Leber *et al.*, 1999) in eNOS. The possible significance of zinc as a metal center will be discussed from the aspects of struc-

ture and conformation, and various hypotheses regarding the role of zinc in NOS function will be presented later.

A summary of the properties of the three isoforms of nitric oxide synthase is found in Table I. A more comprehensive discussion of these structural and enzymatic parameters, not discussed in the limited space of this review chapter, can be found in the review by Raman *et al.* (2000).

Prosthetic Groups and Cofactors of Nitric Oxide Synthases

Flavin Adenine Dinucleotide and Flavin Mononucleotide

STOICHIOMETRY

The discovery of flavins in the partially purified preparations of nNOS, either from porcine cerebellum (Mayer *et al.*, 1991) or from stably transfected HK293 cells (Bredt *et al.*, 1991), or in preparations of iNOS from murine macrophages (Hevel *et al.*, 1991; Stuehr *et al.*, 1991) was the first indication that the NOS enzymes might resemble the cytochrome P-450 reductase-mediated systems. Hevel *et al.* (1991) and Stuehr *et al.* (1991) reported a stoichiometry of ~ 1 mol per mol each of FAD and FMN per 130-kDa subunit for iNOS, and Mayer *et al.* (1991) found between 0.6 and 0.9 mol per mol each of FAD and FMN per 160-kDa subunit of porcine nNOS. Bredt *et al.* (1991) did not present data supporting their contention that FAD and FMN are present in stoichiometric amounts in cloned nNOS expressed in HK293 cells, but they were the first to show the sequence homology between the C-terminal 641 residues of nNOS and NADPH-

cytochrome P-450 reductase. These investigators also recognized that this 58% homology (36% identity) identified nNOS as a member of a class of flavoproteins, including sulfite reductase (Siegel and Kamin, 1968) and NADPH-cytochrome P-450 reductase, that contain binding sites for NADPH, FAD, and FMN within the same polypeptide (Porter and Kasper, 1986).

OXIDATION-REDUCTION AND MECHANISTIC ASPECTS

The mechanisms of action of NADPH-cytochrome P-450 reductase and sulfite reductase require a shuttling of electrons between the FAD and FMN prosthetic groups, and a similar mode of transfer was suggested for NOS in the Bredt *et al.* (1991) paper. At the same time, the authors stated that the N-terminal half of nNOS showed no resemblance to any protein known at that time. Perhaps this was a message to investigators that even more interesting findings were to come. It could have been surmised from the striking sequence homology between the C-terminal half of nNOS and NADPH-cytochrome P-450 reductase that the binding site for tetrahydrobiopterin, the only other cofactor known to be required for NOS activity in 1991, was more likely to be in the N terminus (see later).

Marletta's laboratory suggested a role for the flavin semiquinone in catalyzing the one-electron chemistry that must accommodate the formation of NO \cdot , a five-electron oxidation process (Hevel *et al.*, 1991). In the first studies of an FAD- and FMN-containing enzyme, a mechanism for NADPH-cytochrome P-450 reductase catalysis was proposed (Masters *et al.*, 1965a,b) in which the semiquinone redox state was the most oxidized partner of the catalytic cycle and electrons were shuttled between one- and three- or

Table I Properties of Mammalian NOS Isoforms

Structural and enzymatic parameters	Active homodimers		
	nNOS (NOS I)	eNOS (NOS III)	iNOS (NOS II)
Subunit molecular mass	160 kDa	135 kDa	125–130 kDa
Inducibility	Constitutive	Constitutive	Inducible
Calmodulin binding	$\sim 30 \times 10^{-9}$ M	$\sim 30 \times 10^{-9}$ M	Subunit-like ($\geq 30 \times 10^{-9}$ M)
Cofactors	H ₄ B, FAD, FMN, heme, Zn	H ₄ B, FAD, FMN, heme, Zn	H ₄ B, FAD, FMN, heme, Zn
Substrates	NADPH, L-arginine, oxygen	NADPH, L-arginine, oxygen	NADPH, L-arginine, oxygen
Protein variants	μ , α , β , γ tissue-specific isoforms	—	—
Posttranslational modifications	Specific phosphorylation sites present	Myristoylation, palmitoylation, phosphorylation sites present	Specific phosphorylation site present
Sources of superoxide formation	Heme domain, reductase domain	Mainly heme domain	Mainly reductase domain
Protein-protein interactions	PSD-95, caveolin3, phosphofructokinase M	Caveolin1, HSP 90, CAT-2, bradykinin receptor	—
Major physiological function	Neurotransmission	Vasodilatation	Cytotoxicity
Role in disease	Stroke, muscular dystrophy, ischemia-reperfusion injury	Endothelial dysfunction, hypercholesterolemia, hypertension	Toxic shock, inflammation, autoimmune disease

between two- and four-electron-reduced states. The possibility that such a mechanism might apply to the NOS isoforms was brought to light by the report of Stuehr and Ikeda-Saito (1992) in which they provided evidence for a $g = 2.0$ electron paramagnetic resonance (EPR) signal that disappeared on reoxidation of the sample by ferricyanide. This led this author (Masters, 1994) to propose an oxygenation cycle for NOS that involves redox states of the heme and flavins by analogy with the known interactions of NADPH–cytochrome P-450 reductase with cytochromes P-450 or artificial electron acceptors. In this scheme, the various redox states for the flavoprotein domain are proposed to interact with the appropriate substrate-bound form of NOS during the oxygenation process. Although this scheme did not include a redox role for H_4B , the cation radical form of $H_3B\cdot$ could be invoked as an intermediate in the odd-electron chemistry of the overall NOS reaction mechanism (see later).

In a study of all three isoforms, Martásek *et al.* (1999) showed that the flavoprotein-catalyzed reduction of cytochrome *c* by all three NOS isoforms can be compared to that of NADPH–cytochrome P-450 reductase under similar conditions. The turnover numbers for nNOS and eNOS in the reduction of artificial electron acceptors, such as cytochrome *c*, are minimal in the absence of Ca^{2+}/CaM . The addition of Ca^{2+}/CaM to nNOS results in a 10- to 15-fold increase in cytochrome *c* reduction ($\sim 5000 \text{ min}^{-1}$), which is ~ 1.6 times the rate of NADPH–cytochrome P-450 reductase-catalyzed cytochrome *c* reduction (Martásek *et al.*, 1999). On the other

hand, although eNOS cytochrome *c* reductase activity is increased >2 -fold in the presence of Ca^{2+}/CaM , its activity is only $\sim 16\%$ that of the reductase (Martásek *et al.*, 1999, Fig. 1). Inducible NOS, in the absence of added Ca^{2+}/CaM , catalyzes cytochrome *c* reduction at the same rate as Ca^{2+}/CaM -activated nNOS. The rates of cytochrome *c* reduction can be ranked accordingly: iNOS = nNOS \gg eNOS. In other experiments in which electron transfer to the heme domain is measured by reduced CO difference spectroscopy (binding of CO is possible only with reduced heme), it is apparent that eNOS is the most “tightly coupled” of the NOS isoforms: NADPH reduces the heme to the same extent as dithionite, whereas in the case of nNOS, approximately 70% of the heme is reduced by NADPH, and in iNOS, approximately 30% reduction occurs. These results have interesting implications with respect to the structure–function relationships among the various NOS isoforms due to the marked differences in sequence in specific regions of the flavoprotein domains of the three NOS isoforms.

Advantage was taken of sequence alignments by Salerno *et al.* (1997) to show additional sequences in the flavoprotein domains of the constitutive NOS isoforms that were not present in inducible NOS, flavodoxins, or NADPH–cytochrome P-450 reductase (Salerno *et al.*, 1997). Homology-based molecular modeling showed the superimposition of the backbone structures of iNOS and NADPH–cytochrome P-450 reductase on the backbone of *Desulfovibrio vulgaris* flavodoxin, the structural homolog of the FMN binding mod-

Figure 1 A ribbon diagram of the overall structure of the nNOS FAD-binding domain. The structure comprises three functional domains: the NADP(H)-binding domain is shown in olive green, the FAD-binding domain in green, and the connecting domain in red. The N and C termini are indicated, and the cofactors are shown in ball-and-stick form. See color insert.

ule of NOS that it most resembles. Most of the modeled eNOS and nNOS backbone structures can also be superimposed, except for the region representing an ~45-amino acid insertion in the constitutive isoforms, eNOS and nNOS. These comparisons suggested the possibility that a loop, consisting of a preponderance of positive charges and located within the FMN binding site only in eNOS and nNOS, could be involved in the binding interactions required for calmodulin activation of the constitutive NOS isoforms. The hypothesis was put forth that this insertion could represent an "autoinhibitory loop" that sterically hinders the binding of calmodulin through binding domain overlap or through allosteric effects.

To test this hypothesis, Salerno *et al.* (1997) used peptides, the sequences of which were derived from the 45-amino acid insert in eNOS, to inhibit the formation of NO \cdot or the binding of ^{125}I -calmodulin or $[^3\text{H}]\text{N}^G$ -nitro-L-arginine. The most potent inhibitory sequences were those containing the RRKRK motif. In a control experiment, limited trypsinolysis was performed, and it was determined that cleavage of exposed lysine residues (Lys-856 in nNOS and Lys-545 in eNOS) occurred in the presence of Ca^{2+} /calmodulin binding but not in its absence. Since these residues exist within the putative "autoinhibitory loop," the latter experiment suggests that conformational changes involving this loop occur during calmodulin activation of constitutive NOS isoforms. This activation is precluded in the inducible isoform due to the absence of this loop sequence. Additional support for such conformational changes has come from the reports of Sheta *et al.* (1994), Gachhui *et al.* (1996), Narayanasami *et al.* (1997), and Schmidt *et al.* (1992) in which Ca^{2+} /calmodulin-induced fluorescence changes were measured.

Subsequent to this report, several additional studies have appeared that support the role of such a modulatory sequence. In a study from Stuehr's laboratory (Adak *et al.*, 1999) in which the aim was to study the role of the nNOS reductase domain cluster of acidic residues, two conserved acidic residues (Asp-918 and Glu-919) and one conserved aromatic residue (Phe-892) were mutated. The authors examined flavin binding, conformational changes, electron transfer reactions, calmodulin regulation, and catalytic activities to determine the effects of these mutations. Although FMN binding was destabilized, the binding of substrate, cofactor, and calmodulin were unaffected when the nNOS was reconstituted with FMN, indicating that the defect was isolated to the FMN-binding module. Coincidentally, these studies established the flow of electrons from NADPH to FAD to FMN to heme. FMN binding seemed to suppress NADPH binding, but its absence did not affect electron transfer to 2,6-dichlorophenolindophenol (DCIP) or potassium ferricyanide. FMN removal increased the rate of ferricyanide reduction, as did the binding of Ca^{2+} /calmodulin, leading the authors to conclude that Ca^{2+} /calmodulin binding is equivalent to FMN removal and is consistent with the increase in flavin fluorescence being restricted to the FMN module of nNOS. These authors offer the conclusion that the

FMN module is the key response element in nNOS responsible for regulating electron transfer to the various acceptors, including the NOS-bound heme. These authors also offer the possibility that their mechanism could involve the insert in nNOS proposed by Salerno *et al.* (1997) to regulate Ca^{2+} /calmodulin binding affinity.

Simultaneously, Daff *et al.* (1999) showed that deletion mutants of nNOS, in which 40 and 42 amino acids were removed from the putative autoinhibitory loop (Salerno *et al.*, 1997), retained maximal NO \cdot synthesis activity at lower concentrations of Ca^{2+} than the wild-type nNOS. Also, remarkably, the mutants retained 30% of their activities in the absence of Ca^{2+} /calmodulin, suggesting that this insert is involved in inhibiting electron transfer from FMN to heme in the absence of Ca^{2+} /calmodulin and in destabilizing Ca^{2+} /calmodulin binding when Ca^{2+} levels are low in nNOS, supporting its role as an autoinhibitory loop.

The generation of chimeric constructs, utilizing sequences of the constitutive NOS isoforms and inducible NOS, by the laboratories of Nathan (Ruan *et al.*, 1996), Ortiz de Montellano (Nishida and Ortiz de Montellano, 1998), and Stull (Lee and Stull, 1998) also presented evidence that the Ca^{2+} /calmodulin binding domain as well as elements in both the reductase and oxygenase domains are responsible for the Ca^{2+} independence of iNOS. None of these studies is inconsistent with the existence of an autoinhibitory binding loop in the constitutive NOS isoforms.

The author's laboratory, in collaboration with Dr. J.-J. Kim, has been involved in crystallographic studies of flavin-containing constructs of the NOS isoforms to follow their reports of the crystallization (Djordjevic *et al.*, 1995) and structural determination (Wang *et al.*, 1997) of NADPH-cytochrome P-450 reductase. More recently, it has been possible to crystallize and solve the structure of the FAD binding domain containing nNOS residues 963–1412 obtained by trypsinolysis of the holoenzyme shown in Fig. 1. In support of the conclusions of Adak *et al.* (1999), the FAD binding domain is not unique structurally. In fact, when the structures of the nNOS–FAD binding domain and NADPH-cytochrome P-450 reductase are overlaid, the FAD binding domains are virtually superimposable. This means that this domain, which exhibits considerable sequence similarity with two NADPH-dependent flavoproteins, ferredoxin–NADP $^{+}$ reductase and NADH-cytochrome b_5 reductase, contains binding sites for both NADPH and FAD and binds FAD in an extended conformation. As in NADPH-cytochrome P-450 reductase, the isoalloxazine ring is between the FAD and NADP(H) binding subdomains, and the remainder of the FAD molecule lies between the FAD binding and connecting domains. There are aromatic stacking residues on both sides of the nNOS FAD isoalloxazine ring and on one side of the adenine ring.

Of course, the absence of the FMN binding domain in this crystal structure leaves many of the questions raised in the previous discussion unanswered. By default, the structural homology of the FAD binding domain with NADPH–

cytochrome P-450 reductase leaves the FMN binding domain highly suspect as the seat of the modulation of Ca^{2+} /calmodulin regulation. This suggestion is bolstered by the fact that the crystal structures of the heme domain dimers of the NOS isoforms have offered little insight into mechanistic differences.

Iron Protoporphyrin IX

STOICHIOMETRY

When the simultaneous discovery by four separate laboratories of the presence in NOS of iron protoporphyrin IX (heme) was made (McMillan *et al.*, 1992; White and Marletta, 1992; Stuehr and Ikeda-Saito, 1992; Klatt *et al.*, 1992), the question of the site of substrate oxygenation was solved, but the role of tetrahydrobiopterin became even more mystifying. Since the stoichiometry of flavin binding was already known (see earlier), it was a simple matter to establish the relative stoichiometry of heme binding to NOS. In all studies reported in 1992, the binding of one heme group per monomer was determined, regardless of the NOS isoform. Of interest from a mechanistic viewpoint was the finding that the difference absorption spectrum, determined in the presence of reducing agent (dithionite) and CO and compared to the oxidized form, revealed an absorption maximum at ~ 445 nm. As is the case with all cytochromes P-450 known, this absorption maximum indicates the presence of a cysteine thiolate ligand to the heme iron.

OXIDATION-REDUCTION, MECHANISTIC ASPECTS, AND STRUCTURAL PROPERTIES

Because the cytochromes P-450 are involved in the oxygenation of a variety of endogenous and exogenous substrates, the analogies with the nitric oxide synthesis reaction began to unfold, since it was already known that the C terminus of nNOS was highly homologous to NADPH-cytochrome P-450 reductase. Almost immediately, these analogies led to speculation regarding the oxidation-reduction mechanisms of NOS catalysis by a number of workers, including Marletta (1993; Hurshman *et al.*, 1999), Griffith and Stuehr (1995), Masters (1994), and Korth *et al.* (1994), among others. Evidence was presented by McMillan and Masters (1993) and Pufahl and Marletta (1993), using L-arginine or N^G -hydroxy-L-arginine perturbation of the heme spectrum of NOS (optical absorption difference spectroscopy), that the spectral signature of a high spin heme was obtained on the addition of L-arginine to NOS. These results, which were reminiscent of those obtained with cytochromes P-450 and various substrates and heme ligands (Lewis, 1996; Schenkman *et al.*, 1981), indicated that these compounds were perturbing the structures of NOS in the environment of the heme. The development of a high-spin ("type I") spectrum precluded direct ligation to the heme iron. Other nitrogenous ligands, such as imidazole (McMillan and Masters, 1993), on the other hand, produced low-spin shifts in the binding spectra, indicating direct ligation to

the heme iron. Given these interactions, it was concluded that the interaction of substrate with heme indicated its involvement in the oxygenation process, thus diminishing the role of tetrahydrobiopterin in this respect.

As mentioned in the review by Raman *et al.* (2000), there were actually four important observations that supported the notion that NOS isoforms might bear some similarity to the cytochrome P-450 family of enzymes: (1) the similarity of the domain structure to the cytochrome P-450 from *Bacillus megaterium*, a self-sufficient fatty acid-metabolizing monooxygenase consisting of a heme domain and flavin domain (FAD- and FMN-containing) in a single polypeptide (Narhi and Fulco, 1987); (2) the spectroscopic properties, similar to members of the cytochrome P-450 family, alluded to above; (3) sequence similarity between the NOS and cytochrome P-450 family members within a nine-residue sequence believed to be involved in heme ligation and containing the cysteine thiolate (McMillan *et al.*, 1992); and (4) the capability of the cytochromes P-4503A to catalyze $\text{NO}\cdot$ formation from N^G -hydroxy-L-arginine, the obligatory intermediate in NOS catalysis. It is well to bear in mind one major difference, however, in the binding sites for NOS enzymes as compared to those for cytochromes P-450. Catalysis by NOS of L-arginine monooxygenation already defines the environment of the substrate as being highly polar, due to the guanidinium function of L-arginine, whereas cytochromes P-450 catalyze the hydroxylation of hydrophobic substrates such as steroids, fatty acids, prostaglandins, and a myriad of drugs and environmental toxicants, all of which are hydrophobic compounds.

On the revelation of the structure of iNOS by Crane *et al.* (1998) and that of eNOS by Raman *et al.* (1998), it was apparent that a unique fold with no similarities to previous P-450 structures (all of bacterial origin) exists in iNOS and eNOS. The cysteine thiolate ligand resides on the proximal side of the heme in both cytochromes P-450 and NOS, but in cytochromes P-450, a helix containing residues that participate in catalysis occurs in proximity to the heme iron. NOS, in contrast, contains a β strand on the distal side of the iron protoporphyrin ring. As in many other enzymes that contain metal-bound thiolates, cytochromes P-450 (Poulos *et al.*, 1985) and NOS isoforms (Crane *et al.*, 1998; Raman *et al.*, 1998; Fischmann *et al.*, 1999; Li *et al.*, 1999) can accept hydrogen bonds from neighboring backbone NH groups due to the formal negative charge of these metal-thiolate complexes.

In examining the distal heme environment and the planar structure of the bound heme, it can be seen that the heme ring is distorted into a concave configuration with the bowl facing the distal heme pocket. The heme is buried within this pocket with little solvent accessibility except for one of the heme propionates, but a large substrate/cofactor access channel allows solvent access to both the active site and heme, as well as the tetrahydrobiopterin binding site. Tetrahydrobiopterin binding, however, has no effect on the nonplanarity of the heme, since H_4B -free eNOS (Raman *et al.*, 1998) reveals

the same ring distortion. Possible consequences of this heme ring distortion are discussed in detail by Raman *et al.* (2000). In addition to the obvious nonplanar configuration, NOS heme exhibits a different diastereomeric orientation relative to the methyl and vinyl side chain substituents of the porphyrin ring. The iNOS crystal structure shows that the heme plane facing the thiolate ligand (proximal) is flipped 180° compared with cytochromes P-450 (Crane *et al.*, 1997). In addition, the eNOS structure (Raman *et al.*, 1998) indicates that the heme orientation is similar to that seen in peroxidases, although these enzymes utilize a histidine residue as the proximal ligand. Despite these facts, chloroperoxidase and eNOS show similarities in EPR signatures for ligand binding, indicating polar distal heme environments in both types of enzymes. Comparison of the Soret circular dichroism structures showed that the spectra were inverted with respect to one another, suggesting a different heme orientation that was later confirmed in the structures (C. S. Raman, P. Martásek, and B. S. S. Masters, unpublished observations, 1995; Raman *et al.*, 2000; Andersson and Peterson, 1995).

The recognition of the substrate, L-arginine, is a far more important consideration in the NOS isoforms, because of the high degree of specificity of the active site of NOS compared to cytochromes P-450, which generally accommodate a large number of hydrophobic substrates of differing structures (with the exception of the steroid hydroxylases that exhibit stereo- and regioselectivity). L-Arginine is bulky and contains a large and extended surface (length 6.3 Å, volume 195 Å³), and, of course, it is charged owing to its guanidinium side chain. Substrate recognition by NOS isoforms must accommodate the strong polarity of L-arginine, which is the most hydrophilic of all amino acids found in proteins.

With the exception of one residue, Val-338 in eNOS, which makes a van der Waals contact with the aliphatic portion of L-arginine, there are no other hydrophobic groups in spatial contiguity with the substrate. In eNOS, the guanidinium side chain of L-arginine is hydrogen bonded to the active site Glu-363, which is a typical side-chain interaction in many proteins; this result is predicted by the site-directed mutagenesis studies of Chen *et al.* (1997; in eNOS) and Gachhui *et al.* (1997; in iNOS). The binding of L-arginine is nearly identical in both iNOS and eNOS, as shown in the crystal structures of the substrate-bound heme domain dimers (Crane *et al.*, 1998; Raman *et al.*, 1998; Fischmann *et al.*, 1999; Li *et al.*, 1999), and the residues participating in hydrogen bonding are highly conserved. The Raman *et al.* (2000) review shows hydrogen bonding interactions of eNOS with L-arginine, seven of which are with protein residues, one with water, and one with the propionic side chain of heme. In addition, a number of van der Waals contacts contribute to substrate binding (Raman *et al.*, 2000). In experiments performed in collaboration with Hoffman's laboratory, the Masters' laboratory was able to determine the distance between the guanidinium nitrogen of both L-arginine (~4 Å) and N^G-hydroxy-L-arginine (3.8 Å) to the heme iron in nNOS (Tierney *et al.*, 1998, 1999) using Q-band pulsed

¹⁵N electron nuclear double resonance (ENDOR) spectroscopy and employing ¹⁵N-labeled substrates. The data for L-arginine were actually published before the crystal structures were revealed, exhibiting the power of this technique for obtaining structural information.

In addition to the binding of L-arginine, the heme domain also contains the binding site for H₄B. This site also appears to be identical among the various isoforms, based on the available crystal structure data.

Tetrahydrobiopterin

STOICHIOMETRY

The requirement for tetrahydrobiopterin (H₄B) for catalysis of NO• formation was established first for the inducible NOS from macrophages by Tayeh and Marletta (1989) and Kwon *et al.* (1989) and subsequently in neuronal NOS by Mayer *et al.* (1990) and Schmidt *et al.* (1992). Although the content of H₄B in tissue-purified NOS preparations varies greatly, it is now clear that the stoichiometry for binding is one H₄B per monomer, based on X-ray crystallographic studies to be discussed later. On the successful high-level expression of the NOS isoforms in *Escherichia coli* (McMillan and Masters, 1995; Roman *et al.*, 1995; Martásek *et al.*, 1996), in which the absence of the GTP cyclohydrolase precludes the biosynthesis of H₄B, it has been possible to examine H₄B-free preparations of the NOS isoforms. It is now well established from many studies that these preparations are inactive without the addition of exogenous H₄B (Roman *et al.*, 1995; Vásquez-Vivar *et al.*, 1998, 1999; Hurshman *et al.*, 1999). Many studies have attempted to delineate the role of H₄B in the mechanism of NOS, and certain aspects of the binding and action of this pterin cofactor have been compared to the aromatic amino acid hydroxylases and other pterin-utilizing enzymes. Raman *et al.* (1998) have discussed these comparisons in detail, and similarities have been drawn between H₄B binding by NOS and those enzymes that utilize pterin as a substrate (dihydroneopterin aldolase, dihydropteroate synthase, thymidylate synthase, and molybdopterin oxidoreductase) and not as a cofactor (aromatic amino acid hydroxylases). Also, in light of the fact that the cytochrome P-450 systems, with which the NOS isoforms share much similarity in mechanism, do not require H₄B, it is important to determine its role in these complex enzymes.

OXIDATION–REDUCTION AND/OR FUNCTIONAL ROLE

The actual functional significance of H₄B in NOS catalysis remains unsolved. However, studies utilizing different approaches to probe the structure–function aspects of NOS isoforms are invoking an oxidation–reduction (redox) role for H₄B, while not involving this cofactor in the activation of oxygen for the oxygenation of either L-arginine or N-hydroxy-L-arginine. It has been known for some time that the reduced form of pterin is the only redox state that supports NO• formation catalyzed by any of the NOS isoforms. Klatt *et al.* (1994) examined the binding site of tetrahy-

drobiopterin, using ^3H -labeled (6*R*)-5,6,7,8-tetrahydro-L-*biopterin* as a radioligand and a variety of pteridine derivatives as antagonists. These investigators also found that the affinity of porcine brain nNOS for H_4B was increased sixfold in the presence of L-arginine ($K_D = 37 \text{ nM}$), a phenomenon that was not to be thoroughly understood until the structures of the heme domains of NOS were solved (see later).

On examination of the structures of the heme domains of inducible NOS or endothelial NOS (Crane *et al.*, 1998; Raman *et al.*, 1998; Fischmann *et al.*, 1999; Li *et al.*, 1999), the nature of the binding of H_4B to NOS may be better understood. In particular, the report of Raman *et al.* (1998) focused on the complex hydrogen-bonding system involving H_4B , including interactions with the heme prosthetic group and the various amino acid residues of NOS within hydrogen-bonding distance of H_4B , and the impact of these interactions with the substrate, L-arginine. In addition, Raman *et al.* (1998) noted that in one of their solved crystal structures, obtained with the inhibitor *S*-ethylisothiourea (SEITU) bound in the substrate binding site, L-arginine was unexpectedly found in the H_4B binding site (Fig. 2) (Raman *et al.*, 1998, 2000). This led the authors to suggest that this site accommodated a structure similar to a cation radical, mimicked by the planar guanidino group of L-arginine.

The prior report of Bec *et al.* (1998) had already suggested an enzymatic basis for implicating the $\text{H}_3\text{B}^\bullet$ in electron transfer by showing differences in the decay of the

$\text{Fe}^{\text{II}}\text{O}_2$ complex of nNOS in single turnover studies in the presence and absence of H_4B . The studies by Bec *et al.* (1998) were performed at lower temperature (-30°C) to stabilize the oxy complex of nNOS, and spectral intermediates were directly compared to cytochrome P-450 2B4 under the same experimental conditions. Spectral comparisons led to the conclusion that the decay of the oxyferrous complex of NOS produces a discernible proportion of high-spin ferric heme, not seen in the concurrent P-450 spectra obtained in the Bec *et al.* (1998) experiments but resembling those seen with other ferrous complexes of cytochromes P-450 (Dawson *et al.*, 1983; Dawson and Sono, 1987) for “hyperporphyrin” species. Bec *et al.* (1998) determined that H_4B -free and H_4B -bound NOS produced similar spectral changes on the binding of O_2 at -30°C , and the autooxidation of these species resulted in low-spin ferric heme. In contrast, although L-arginine alone did not produce the blue-shifted oxygen complex observed in H_4B -bound nNOS, and the spectra resembled those obtained with the H_4B -free nNOS in the absence of L-arginine, the presence of both substrate and cofactor resulted in the formation of high-spin ferric heme. Thus, the decay of the oxygenated, L-arginine-bound intermediate in the presence of added H_4B , but not in its absence, led to the conclusion that $\text{H}_3\text{B}^\bullet$ could be formed as a result of a one-electron donation from the reduced pterin to the oxygenated species. This observation could also be explained by the unique interactions between H_4B , the heme prosthetic group, and the substrate, L-arginine, revealed in the crystal structures or, alternatively, by interaction with the flavins of NOS.

Mayer and colleagues (Reithmuller *et al.*, 1999) have also reported that the 5-methyl analog of H_4B is functionally active in NOS but cannot react with molecular oxygen or stimulate phenylalanine hydroxylase activity. Although previous experiments from Kaufman and colleagues (Giovanelli *et al.*, 1991) had shown that H_4B in catalytic amounts could support NOS activity, these investigators also showed that no recycling of exogenous H_4B occurred during NOS turnover. Furthermore, these investigators later stated that their previous results did not preclude the possibility that tightly bound H_4B could participate in recycling (Campos *et al.*, 1992). Using limiting concentrations of NADPH and a regenerating system for NADPH, Kaufman's laboratory (Witteveen *et al.*, 1996) was able to determine H_4B levels formed from qH_2B during turnover of recombinant nNOS, by coupling its formation to the phenylalanine hydroxylase reaction and detecting the amount of H_4B -dependent conversion of $[\text{H}]$ phenylalanine to $[\text{H}]$ tyrosine. The reduction of qH_2B was inhibitable by diphenyliodonium, a potent, nonspecific flavoprotein inhibitor, but was slightly stimulated by inhibitors of the oxygenase (heme) domain, such as 7-nitroindazole or *N*-nitro-L-arginine, indicating that it was catalyzed by the flavoprotein domain of nNOS.

Witteveen *et al.* (1999), using the same method of measuring the formation of H_4B , purported to show that single-turnover oxidation of H_4B is stimulated by L-arginine in the presence of $\text{Ca}^{2+}/\text{CaM}$, and that reduction of the oxidation

Figure 2 L-Arg is a structural mimic of H_4B at the pterin-binding site when SEITU is bound at the active site ($-\text{H}_4\text{B}$, + SEITU data). L-Arg binds to the pterin site and exquisitely mimics the H_4B interaction with eNOS (Fig. 3). The specific interaction of the potent inhibitor, SEITU, at the active site is mediated by a pair of bifurcated hydrogen bonds to Glu-363. Two water molecules bridge the inhibitor and heme propionate. The ethyl group of the inhibitor forms nonbonded contacts with Val-338 and Phe-355. The ureido sulfur is positioned 3.5 and 4.0 Å above the heme pyrrole B-ring nitrogen and the heme iron, respectively. See color insert.

product of H_4B by the flavoprotein activity is consistent with a role for pterin as an electron donor in product formation. Witteveen *et al.* (1999) were unable to define this role, however. The nNOS preparation used in these experiments (Witteveen *et al.*, 1996, 1999) was expressed in and purified from human kidney 293 cells, in which H_4B can be biosynthesized. Therefore, the preparations contain varying amounts of the pterin cofactor, and, in the later publication (Witteveen *et al.*, 1999), these authors state that the H_4B content is “typically 0.5 mol/mol subunit” from high-pressure liquid chromatography analysis of oxidized samples. These authors quoted the report of Bec *et al.* (1998), who suggested that H_4B is involved in supplying the single electron required for reduction of ferric heme iron superoxide to the ferric heme iron peroxo species during L-arginine conversion to *N*-hydroxy-L-arginine from their single-turnover experiments. On the basis of this requirement for only one electron, Bec *et al.* (1998) formally represented the intermediate pterin species as H_3B^\bullet , the trihydrobiopterin radical.

Also in 1999, Hurshman *et al.* from Marletta's laboratory performed rapid freeze-quench electron paramagnetic resonance spectroscopy to monitor the reaction of reduced iNOS heme with O_2 in the presence and absence of substrate. These experiments revealed the formation of a transient species, while heme was oxidized at a rate of $\sim 15\text{ s}^{-1}$, with a $g = 2.0$ EPR signal. The anisotropic properties of this signal are typical of an organic radical with $S = \frac{1}{2}$. When the iNOS heme construct is reconstituted in the presence of N-5 ^{14}N - and ^{15}N -substituted H_4B , the spectra reveal a hyperfine interaction of the unpaired electron with the pterin N-5 nitrogen, identifying the radical as the one-electron oxidized form of the bound H_4B (the trihydrobiopterin radical, H_3B^\bullet). In the presence of L-arginine, the radical accumulates to $\sim 80\%$ of the total iNOS heme concentration, but *N*-hydroxy-L-arginine prevents its formation, limiting it to $\sim 3\%$. The rate of formation of the radical is $15\text{--}20\text{ s}^{-1}$, independent of substrate, and its subsequent decay rate is $0.12\text{--}0.7\text{ s}^{-1}$, depending on the substrate. Furthermore, the $g = 2.0$ signal is not observed in the absence of pterin. The authors argue that all of their data implicate the $g = 2.0$ signal as a NOS-bound pterin radical. Pterin radicals have been produced chemically under acidic conditions by reacting oxidants with reduced pterins or by comproportionation of tetrahydropterin and dihydropterin. The chemical and electronic structure of the pterin organic radical formed in the studies of Hurshman *et al.* (1999), however, cannot be determined from the X-band EPR experiments, and the representation of the radical form as H_3B^\bullet does not designate whether it is cationic or neutral. In addition, three-syringe double mixing experiments by Hurshman *et al.* (1999) showed that the radical does not react with either L-arginine or *N*-hydroxy-L-arginine (NHA), thus negating the possibility that a fast reaction of the latter intermediate with the pterin radical occurs. On the other hand, the presence of NHA could prevent the one-electron oxidation of H_4B by reducing the ferrous-dioxygen complex ($\text{Fe}^{2+}\text{O}_2^{\cdot-}$) by single electron transfer, but there is no evidence for NHA \cdot formation in these experiments. Finally, it

should be cautioned, as the authors (Hurshman *et al.*, 1999) have correctly done, that these results, obtained with the iNOS heme domain dimer, may not be extrapolatable to the holoenzyme. The presence of reduced flavin cofactors in the holoenzyme could complicate the formation and/or decay rates of the putative H_3B^\bullet radical. Nevertheless, it is tempting to entertain the possibility, suggested by the turnover experiments of Bec *et al.* (1998) and the crystallographic results of Raman *et al.* (1998), that the H_3B^\bullet radical is involved in electron transfer in NOS to the Fe^{2+}O_2 complex. The answers await development of the appropriate technology to examine this mechanistic possibility more directly and to identify the nature of the radical unequivocally.

Zinc Tetrathiolate Metal Center

STOICHIOMETRY

The determination of the 1.9-Å-resolution X-ray crystal structure of the heme domain dimer of endothelial NOS by Raman *et al.* (1998), in a collaborative study between the laboratories of Poulos and Masters, resulted in the discovery of zinc as the metal constituent of a tetrathiolate center (Fig. 3; see earlier). The beautiful symmetry of the zinc-bound form of eNOS, that is, the equal distance (21.6 Å) of the ZnS_4 center to each of the hemes, which are 34 Å apart in the dimer, and the equal distance (12 Å) from each of the

Figure 3 The ZnS_4 metal center and its relationship to H_4B . Ser-104 is part of the loop containing the cysteine ligands and hydrogen bonds to the C-6 side chain of pterin. The stereospecific recognition of H_4B by NOS is dictated by the substitution at the C-6 position. See color insert.

pterin cofactors, which form an equilateral triangle with zinc, argues for biological significance and chemical stability. On further examination, Raman *et al.* (1998) discovered that all NOS sequences presently known, from mosquito to human, contain the consensus sequence CX₄C, which constitutes an identical pair of cysteine residues in each of the monomers of NOS involved in the ligation of zinc. Other interesting aspects of this ZnS₄ center are its sequence proximity to the Ser-104 residue that hydrogen bonds to the dihydroxypropyl side chain of tetrahydrobiopterin, which probably ensures the stereospecific recognition of H₄B (see earlier in this review, and Raman *et al.*, 1998).

The report of Miller *et al.* (1999) verified the stoichiometry of one Zn atom per two hemes in holoenzyme preparations of both eNOS and nNOS, utilizing electrothermal vaporization–inductively coupled plasma–mass spectrometry (ETV-ICP-MS) and a spectrophotometric chelation assay with 4-(2-pyridylazo)resorcinol (Crow *et al.*, 1997). Rodríguez-Crespo *et al.* (1999) determined the zinc content of all three isoforms, and although the zinc content was low (~25%) in nNOS, both eNOS and iNOS contained ~70% zinc as measured by inductively coupled plasma atomic emission spectroscopy. Interestingly, these authors showed that treatment of iNOS with 50 mM EDTA during affinity column purification lowered the zinc content to below 15%. In addition, contrary to the results of Perry and Marletta (1998), who reported that reconstitution of iNOS and nNOS with iron increases NO-synthesizing activity, Rodríguez-Crespo *et al.* (1999) showed no effect of Fe²⁺ on eNOS, slightly enhanced activity of nNOS, and a lowering of iNOS activity to ~70%. Perry and Marletta (1998) also reported that both purified iNOS and nNOS contain approximately equal amounts of bound zinc and copper, respectively, and both were reconstituted, after desalting, with FeCl₂, yielding one nonheme iron per monomer. This result led to their proposal that a metal binding site in the vicinity of the H₄B binding site, involving His-652 and Asp-650 residues of nNOS, exists in the NOS isoforms similar to that seen, for example, in lysyl hydroxylase (Pirskanen *et al.*, 1996). This is now known not to be the case from the solved structures of eNOS and iNOS heme domain dimers (Crane *et al.*, 1998; Raman *et al.*, 1998; Fischmann *et al.*, 1999; Li *et al.*, 1999). Furthermore, the mutation of all five conserved histidine residues in endothelial NOS, undertaken by Rodríguez-Crespo *et al.* (1999) to determine if any of these histidines form a nonheme iron-binding site, did not affect the metal content, nor did it influence the ability of exogenous Fe²⁺ to modify the catalytic activity of endothelial NOS.

With the publication of Raman *et al.* (1998), the report of Chen *et al.* (1995) showing that a C99A mutation of human eNOS markedly affected the binding of H₄B peaked the interest of the Masters laboratory and prompted the generation of a comparable mutant, C331A, of rat nNOS (Martásek *et al.*, 1998). The homologous residue in each isoform fortuitously constituted one of the cysteine residues in each monomer involved in Zn binding. Miller *et al.* (1999) also reported the Zn content of the C331A nNOS mutant to be 5

or 19%, based on the stoichiometry of 1:2 zinc:heme in the H₄B-minus and H₄B-plus preparations, respectively, of this mutant. This result confirmed that the C331A mutant was defective in its zinc binding affinity owing to the loss of one-half of the residues involved in Zn binding.

In addition, following the Raman *et al.* (1998) study, a second crystallographic report appeared (Fischmann *et al.*, 1999) in which the crystal structures of human iNOS and eNOS heme domain dimers were determined and a zinc tetrathiolate was found to be a constituent of both isoforms. In their experiments, Fischmann *et al.* (1999) showed the near identity of the oxygenase (“catalytic”) domain structures of the human iNOS and eNOS isoforms. In addition, a second publication from Poulos’ laboratory (Li *et al.*, 1999), showing Zn-free and Zn-replete human iNOS structures (Fig. 4), confirmed a disulfide bond between the symmetry-related Cys-115 residues in the Zn-free preparation. On Zn repletion, the preparation revealed the ZnS₄ tetrathiolate center reported by Raman *et al.* (1998). In their experiments, Li *et al.* (1999) reported that the addition of zinc, in the presence of a strong reducing agent, “strengthened the crystal lattice as indicated by a decrease in cell dimensions and better diffraction” (Li *et al.*, 1999). On the other hand, the original reports of Crane *et al.* (1997, 1998) did not reveal the presence of zinc in their crystallized preparations, perhaps due to the construct used for crystal growth, conditions for growth in the *E. coli* expression system, other factors during purification, and/or the presence of chelators in the buffers used (see Raman *et al.*, 2000). More recently, however, this group has produced a Zn-containing structure of murine iNOS and compared it to that of a Zn-free preparation (Crane *et al.*, 1999). The authors show “swapped,” disulfide-linked (Cys-109A–Cys-109B) intersubunit interactions across the dimer interface in the Zn-free structure and Zn-containing intrasubunit interactions involving N-terminal hairpin hooks in the “unswapped” structure. It is apparent that the Zn-free, swapped structure of Crane *et al.* (1999) has ordered conformation in the region of the Zn binding loop. The authors attribute these differences between their Zn-free structure and that of the disordered structure of Li *et al.* (1999) to the presence of ascorbate in the crystallization and synchrotron data collection buffer. The implications of these findings with respect to the functional role of iNOS, according to Crane *et al.* (1999) and Ghosh *et al.* (1999), will be discussed later. It should be pointed out, however, that in neither of these two publications is there an analysis of zinc content in the preparations utilized for crystallography, leaving the comparison of these structures with respect to zinc content somewhat conjectural.

FUNCTIONAL ROLE

Although there is considerable controversy regarding the function of zinc in the various NOS isoforms, it is generally agreed that profound structural changes occur on zinc binding (Li *et al.*, 1999; Crane *et al.*, 1999), at least in iNOS. Raman *et al.* (1998, 2000) have provided evidence for a structural role for zinc in the NOS isoforms. Their arguments

Figure 4 Stereo view of the $2F_0-F_0$ omit electron density map of zinc-free (right) and zinc-bound (left) structures contoured at 1σ . Maps were calculated by a simulated annealing protocol with the residues shown omitted. A disulfide bond is formed between two symmetry-related Cys⁻¹¹⁵ residues when zinc is lost. Residues 107–144 are disordered in the zinc-free structure, which is obviously indicated by the poor, broken density. For clarity, only side chains of Cys ligands are shown. See color insert.

are based on the location of the ZnS_4 center at the dimer interface and the roles of similar centers in at least six other enzymes in mediating protein–protein interactions or stabilizing intersubunit interactions or oligomerization, for example, aspartate transcarbamylase (Honzatko *et al.*, 1982), p56^{lck}–CD4 interaction (Huse *et al.*, 1998; Lin *et al.*, 1998), and Mss4 (Ostermeier and Brunger, 1999).

The Cys-331A mutant of nNOS, generated by Martásek *et al.* (1998), resulted in the replacement of one of the Zn-binding residues. This mutant was totally inactive until reactivated by overnight incubation with high concentrations of L-arginine, yielding activities comparable to that of wild-type nNOS. These results support the structural role of the intricate network connecting the zinc-binding cysteine residues with H_4B , heme, and L-arginine (Fig. 3). Not shown in this figure for the sake of clarity is the binding of L-arginine to the same propionic acid side chain of the heme that interacts with N-3 and the amine at C-2 of H_4B (Raman *et al.*, 1998).

Raman *et al.* (2000) have also presented a strong case for the unlikelihood that under normal cellular conditions disulfides would substitute for a metal center, including the fact that the cytosol exhibits a highly reducing environment, a situation that does not favor disulfide formation. In fact, except for a few instances in which sulfhydryl–disulfide interchange occurs in redox-active flavoproteins, such as glutathione reductase (Schulz *et al.*, 1978), most disulfide-containing proteins are extracellular. Raman *et al.* (2000) also point out in their review that, although there is no evi-

dence at the present time that the ZnS_4 -encompassing surfaces in NOS isoforms are involved in docking with other proteins, as has been shown for Mss4–rab interactions (Yu and Schreiber, 1995; Ostermeier and Brunger, 1999), the participation of zinc in the formation of a scaffold involved in molecular recognition is highly probable. In addition, the dissociation constants of three proteins binding zinc and one binding iron through $(\text{Cys})_4$ ligands were shown to range from 10^{-9} to 10^{-15} , suggesting the very tight binding of zinc in these varied proteins that exhibit tetrahedral binding geometry.

It is important to keep these comparisons in mind in considering the reported swapped versus unswapped structures reported by Crane *et al.* (1999) and the accompanying biochemical and mutational studies of Ghosh *et al.* (1999). The tantalizing suggestion is made that “correlation of metal ion release with swapping and the ability of Cys109 [in murine iNOS] to switch between zinc coordination and intermolecular disulfide formation may have implications for the regulation of NOS via alteration of dimeric stability and molecular surface properties.” These authors support their suggestion further, stating, “Reactive oxygen species and NO produced during the oxidative burst of activated macrophages alter the cellular redox environment and react specifically with thiol-ligated metal centers (Dempfle, 1996; Lipinski and Drapier, 1997; Piedrafitra and Liew, 1998; Wink and Mitchell, 1998). It will be interesting to determine if there are physiological or pathophysiological circumstances in which this type of switching could occur, in light

of the findings of Li *et al.* (1999) in human iNOS in which powerful reducing conditions, namely, tris(2-carboxyethyl) phosphine (TCEP) in lieu of reduced glutathione, were required to insert zinc into the disordered zinc-free construct prepared by trypsinolysis of the human iNOS heme domain (residues 74–703). In addition, Miller *et al.* (1999) were able to eject zinc from the eNOS or nNOS preparations only in the presence of guanidinium chloride and/or potent reduced oxygen species, such as hydrogen peroxide (H_2O_2). This, of course, does not preclude an isoform-specific response, but these circumstances are subject to confirmation by studies of more physiological situations and are difficult to substantiate.

Regulation of the Expression of Nitric Oxide Synthase Isoforms

Hartmut Kleinert, Jean-Paul Boissel, Petra M. Schwarz, and Ulrich Förstermann

*Department of Pharmacology, Johannes Gutenberg University
Mainz, Germany*

THERE IS A LARGE ARRAY OF REGULATORY MECHANISMS FOR THE EXPRESSION OF THE DIFFERENT NOS ISOFORMS. THE HIGH-OUTPUT NOS II IS NOT ONLY TURNED ON TRANSCRIPTIONALLY, BUT THE STABILITY OF THE TRANSCRIPTS AND THEIR TRANSLATION CAN BE REGULATED DYNAMICALLY. IN ADDITION, THE EXPRESSIONAL LEVELS OF THE SERVOREGULATORY, LOW-OUTPUT ENZYMES NOS I AND NOS III CAN ALSO BE ADJUSTED TO MEET LOCAL DEMAND. THE ORIGINAL PARADIGM THAT NO IS SYNTHESIZED EITHER BY CONSTITUTIVE NO SYNTHASES (NOS I AND NOS III) OR BY THE INDUCIBLE NOS II IS NO LONGER VALID. THIS ADDS TO THE DIVERSITY OF MECHANISMS CONTROLLING NO PRODUCTION IN DIFFERENT CELLS AND TISSUES.

Cellular Expression of the Nitric Oxide Synthase (NOS) Isoforms

The prototypical nitric oxide synthase (NOS) enzyme, NOS I [NOS1, neuronal NOS (nNOS)], is found in neurons. It is a low output NOS whose activity is regulated by Ca^{2+} and calmodulin. NOS I was first purified from rat and porcine cerebellum (Bredt and Snyder, 1990; Mayer *et al.*, 1990; Schmidt *et al.*, 1991). NOS I has a widespread distribution in the central and peripheral nervous systems (Vincent and Hope, 1992). In addition, NOS I mRNA transcripts and/or protein have also been detected in nonneuronal cell types, such as rhabdomyocytes, epithelial cells, mast cells, and neutrophils (for review, see Förstermann *et al.*, 1998). NOS I is likely to play an important role in physiological neuronal functions such as neurotransmitter release, neural development, regeneration, synaptic plasticity, and regulation of gene expression but also in a variety of neurological disorders in which excessive production of nitric oxide (NO) leads to neural injury (Yun *et al.*, 1997).

NOS II [NOS2, inducible NOS (iNOS)] is normally absent from untreated cells, but its expression can be induced

in almost any cell type by bacterial lipopolysaccharide (LPS), cytokines, and other agents. There are also some reports describing constitutive expression of NOS II in certain cells (Casado *et al.*, 1997; Di Cesare *et al.*, 1998; Gath *et al.*, 1996; Park *et al.*, 1996; Sherman *et al.*, 1999). NOS II is a high-output isoform; after induction the translated enzyme produces large amounts of NO in a Ca^{2+} -independent fashion. These high concentrations of NO can inhibit a number of key enzymes that contain iron in their catalytic centers. These include ribonucleotide reductase (rate-limiting in DNA replication), iron-sulfur cluster-dependent enzymes (complex I and II, involved in mitochondrial electron transport), and *cis*-aconitase (in the citric acid cycle) (Nathan and Hibbs, 1991). In addition, high concentrations of NO can directly interfere with the DNA of target cells and cause strand breaks and fragmentation (Fehsel *et al.*, 1995; Wink *et al.*, 1991). A combination of these effects is likely to form the basis of the cytostatic and cytotoxic effect of NO on parasitic microorganisms and tumor cells. Therefore, NO is an essential component of the nonspecific immune defense system (MacMicking *et al.*, 1997). NO produced by NOS II may also interfere with the immune response by regulating

the Th1/Th2 balance (Kolb and Kolb-Bachofen, 1998). In addition to its important role in the immune system, NOS II-derived NO seems to be hepatoprotective (Taylor *et al.*, 1998a). Recent evidence suggests that NOS II also plays an important role in wound healing by enhancing the synthesis of vascular endothelial growth factor and collagen (Frank *et al.*, 1998; Thornton *et al.*, 1998). The impaired wound repair seen in NOS II knockout mice could be reversed by adenoviral-mediated transfer of NOS II (Yamasaki *et al.*, 1998).

However, NOS II is also involved in several types of pathophysiology (Kröncke *et al.*, 1998). For example, NOS II plays an important role in pancreatic β -cell destruction in type I diabetes (Kolb-Bachofen, 1996). In rheumatoid arthritis, NO synthesized by NOS II promotes inflammation and tissue damage (Stichtenoth and Frölich, 1998). High NOS II expression has also been described in patients with multiple sclerosis (Bagasra *et al.*, 1995). The marked fall in blood pressure seen in septic shock is mainly caused by NOS II-derived NO (MacMicking *et al.*, 1995). In inflammatory bowel diseases such as ulcerative colitis and Crohn's disease, intestinal epithelial cells show a marked expression of NOS II (Singer *et al.*, 1996). High NOS II levels are also being found in bronchial epithelial cells in asthma patients, and the NOS II expression seems to correlate with the severity of the disease (Barnes, 1996). Finally, NO produced by NOS II may play a role in cancer development. However, it is not clear at this time whether NO represents a defense mechanism against tumor cell growth or a stimulator of tumor vascularization, perfusion, and thus proliferation (Chinje and Stratford, 1997). High NOS II-mediated NO production has been correlated with decreased metastasis of reticulum cell sarcoma (Xie *et al.*, 1995), whereas in human breast cancer, a correlation has been seen between the expression of NOS II and increased axillary lymph node metastasis (Duenas-Gonzalez *et al.*, 1997). Also, human cancer cells with mutated p53 expressing NOS II showed accelerated tumor growth associated with increased vascular endothelial growth factor expression and neovascularization. This suggests that tumor-associated NO production may promote cancer progression by providing a selective growth advantage to tumor cells with mutant p53 (Ambs *et al.*, 1998a). Similarly, Thomsen *et al.* (1997) described an inhibition of EMT6 murine mammary adenocarcinoma cell growth by 1400W, a specific NOS II inhibitor.

The prototypical NOS III [NOS3, endothelial (eNOS)] enzyme is being found in endothelial cells of many tissues (Pollock *et al.*, 1993). Like NOS I, NOS III is a low-output NOS whose activity is regulated by Ca^{2+} and calmodulin. Endothelium-derived NO is a physiologically significant vasodilator and inhibitor of platelet aggregation and adhesion. In addition, vascular NO can prevent leukocyte adhesion to the endothelium by downregulating the leukocyte adhesion glycoprotein complex CD11/CD18. Finally, NO has also been shown to inhibit the proliferation of vascular smooth muscle cells (for review, see Förstermann *et al.*, 1993, 1994). Therefore, endothelial NO is likely to represent a protective antiatherogenic principle. NOS III expression

has also been demonstrated in several nonendothelial cell types such as neurons of the rat hippocampus and other rat brain regions, some epithelial cells, cardiomyocytes, megacaryocytes and platelets, T cells, and others (for review, see Förstermann *et al.*, 1998).

Whereas transcriptional regulation of NOS II has been established since about 1990, no expressional regulation was originally known for the other two isoforms. More recent evidence suggests, however, that the expression of NOS I and NOS III can also be regulated under various conditions. Therefore, this chapter describes mechanisms of expressional regulation of all three NOS isoforms.

Expressional Regulation of NOS I

Regulation of NOS I Expression by Neurotransmitters

NOS I expression appears to be regulated by changes in neuronal activity (Tascedda *et al.*, 1996). In cerebellar granule cells, the inhibition of the glutamatergic transmission drastically increased NOS I expression (Baader and Schilling, 1996). In neurons of the central nervous system, NOS I is often colocalized with *N*-methyl-D-aspartate receptors (Aoki *et al.*, 1997; Bhat *et al.*, 1995), which are known to mediate effectively Ca^{2+} influx. In addition, NOS I is upregulated in rat cerebellum following phenobarbital treatment (Thompson *et al.*, 1997).

Regulation of NOS I Expression by Steroid Hormones

NOS I expression can also be triggered by sex hormones. It has been demonstrated that estradiol and pregnancy can induce NOS I expression in several tissues of rat and guinea pig (Ceccatelli *et al.*, 1996; Weiner *et al.*, 1994a; Xu *et al.*, 1996). However, in pregnancy, an increase in NOS I mRNA was not apparent in the lamina terminalis and the hypothalamo-neurohypophysial system of the rat (Luckman *et al.*, 1997). In male rats, testosterone treatment has been described to stimulate the expression of the neuronal isoform in the penis (Reilly *et al.*, 1997).

Corticosterone treatment results in an upregulation of heme oxygenase-2 and a concomitant decrease of NOS I transcription in rat brain (Weber *et al.*, 1994). Lithium and tacrine, a cholinesterase inhibitor currently used in the treatment of the symptoms of Alzheimer's disease, increase the expression of NOS I synergistically in the hippocampus of the rat. This effect could be inhibited by corticosterone (Bagetta *et al.*, 1993). In murine N1E-115 neuroblastoma cells, glucocorticoids inhibit NOS I expression by reducing transcription of the NOS I gene (Schwarz *et al.*, 1998).

Regulation of NOS I Expression by Bacterial LPS and Cytokines

A downregulation of NOS I expression has been documented in guinea pig skeletal muscle and rat brain after *in*

vivo treatment with LPS (Gath *et al.*, 1997; Liu *et al.*, 1996). Treatment of rats with LPS or interferon- γ (IFN- γ) also decreased the expression of NOS I in brain, stomach, rectum, and spleen (Bandyopadhyay *et al.*, 1997). In the human T67 astrocytoma cell line, the combination of LPS and IFN- γ did not affect expression of NOS I mRNA (Colasanti *et al.*, 1999). However, an increase in tyrosine phosphorylation of the protein was observed, concomitant with inhibition of NOS I enzyme activity (Colasanti *et al.*, 1999). A transient increase in NOS I mRNA has been reported in the paraventricular nucleus of LPS-treated rats (Lee *et al.*, 1995). NOS I protein expression increased in olfactory bulb neurons during infections with vesicular stomatitis virus (Komatsu and Reiss, 1997). A similar increase was seen when NB41A3 neuroblastoma cells were treated with IFN- γ or interleukin-12 (IL-12) (Komatsu *et al.*, 1996; Komatsu and Reiss, 1997).

Physical Stimuli Regulating NOS I Expression

Several *in vivo* studies in rat suggested a time-dependent increase in NOS I mRNA following hypoxia (Guo *et al.*, 1997; Prabhakar *et al.*, 1996; Shaul *et al.*, 1995). This upregulation may be due to two distinct mechanisms: a general cellular stress response (see below) or a direct activation of the NOS I gene transcription through binding of hypoxia-induced factors to specific *cis*-acting elements, as seen in erythropoietin and several other hypoxia-induced genes (Kvietikova *et al.*, 1995). Putative "BACGTSSK" binding sites for the hypoxia-inducible factor-1 (HIF-1) can be detected along the NOS I genomic sequence, but the functionality of these motifs has not yet been determined. In neurons that constitute the osmoreponsive circuit of the rat hypothalamo-hypophysal system, expression of the NOS I gene was upregulated by changes in plasma osmolarity occurring, for instance, during chronic salt loading (Kadowaki *et al.*, 1994) or water deprivation (O'Shea and Gundlach, 1996). In contrast, in rat kidney, a low-salt diet resulted in an increase in NOS I mRNA with a coordinate upregulation of renal expression of renin and angiotensinogen (Singh *et al.*, 1996a; Tojo *et al.*, 1995). In addition, angiotensinogen gene-knockout mice displayed high level of NOS I in the macula densa of the kidney (Kihara *et al.*, 1997). Also, environmental lighting conditions have been shown to upregulate NOS I in the photoneuronally regulated pineal gland (Spessert *et al.*, 1995).

Regulation of NOS I Expression by Stress in Response to Various Stimuli

NOS I mRNA upregulation has also been observed in neuronal cells in response to several nonspecific stimuli such as heat (Sharma *et al.*, 1997), electrical stimulation (Reiser *et al.*, 1997), light exposure (Goldstein *et al.*, 1997; Spessert *et al.*, 1995), colchicine (Lumme *et al.*, 1997), formalin (Lam *et al.*, 1996), phenobarbital (Thompson *et al.*, 1997),

and allergic substances (Calza *et al.*, 1997). A similar response is observed in the rat paraventricular nucleus and adrenal cortex during immobilization stress (Calza *et al.*, 1993; Tsuchiya *et al.*, 1996) and after mechanical or pathological lesions including spinal cord, axonal, or nerve injuries (Herdegen *et al.*, 1993; Lin *et al.*, 1997; Vizzard 1997), hypophysectomie (Villar *et al.*, 1994), or arterial occlusion leading to local ischemia (Samdani *et al.*, 1997; Zhang *et al.*, 1994). Cellular stress is known to trigger the expression of a number of genes resulting in cellular damage and apoptosis. The observed NOS I upregulation may, in most cases, represent only one component of the normal cellular stress response. Enhanced NOS I expression is often associated with co-induction of transcription factors such as c-jun (Herdegen *et al.*, 1993; Wu *et al.*, 1994) and c-fos (Hatakeyama *et al.*, 1996; Torres and Rivier, 1994).

Developmental Regulation of NOS I Expression

Spatial and temporal NOS I expression patterns occur during the development of the nervous system (Bredt and Snyder, 1994; Keilhoff *et al.*, 1996; Northington *et al.*, 1997) and the lung (North *et al.*, 1994; Xue *et al.*, 1996). These changes seem to correlate with differential susceptibility of the cells at particular developmental stages toward specific inductors, such as nerve growth factor (Holtzman *et al.*, 1996), estrogens (Lizasoain *et al.*, 1996), neurotransmitters, and neurotrophins (Baader *et al.*, 1997). Ogura *et al.* (1996) showed that the NOS I mRNA level was increased in a human neuroblastoma cell line following *trans*-retinoic acid-induced neuronal differentiation. In skeletal muscle, a developmental switch from NOS I to the alternative transcript μ NOS I has been reported during myotube fusion (Silvagno *et al.*, 1996). Moreover, an enhanced expression of NOS I is generally observed with postnatal development and aging (Kanda, 1996; Ma *et al.*, 1997).

Characterization of the 5'-Flanking Sequences of NOS I

The usage of various alternative promoters seems to be the main regulatory mechanism involved in NOS I gene expression (for review, see Boissel *et al.*, 1998). Two different transcriptional clusters have been characterized. A genomic DNA fragment (2370 bp) of the human neuronal NOS I transcriptional cluster has been isolated (Hall *et al.*, 1994) (GenBank U 15666). In its 3' part, this DNA fragment contains potential first exons. This region also contains a TATA box and two inverted CAAT boxes. Potential binding sites for transcription factors [such as activator protein-2 (AP-2), transcriptional enhancer factor-1 (TEF-1), M-CAT binding factor (MCBF), cAMP-responsive element binding protein (CREB)/activating transcription factor (ATF)/cFOS, human analogs to avian acute leukemia virus E26 oncogene (ETS), nuclear factor 1 (NF-1), and nuclear factor- κ B (NF- κ B)-like sequences] are found. In the human NOS I testis transcrip-

tional cluster, located between exons 3 and 4, analyses of 1800 bp upstream of the Tex 1 exon (GenBank U 66360) and 1705 bp upstream of the Tex 1b exon (GenBank U 66361) indicate that the two genomic regions lack a typical TATA box (Wang *et al.*, 1997). A CAAT box is located 330 bp upstream from exon Tex 1b. Numerous potential *cis*-acting DNA elements have been detected: Sp-1, ATF/CRE-like sequences, NF- κ B, AP-1, and AP-2. In addition, a variety of *cis*-regulatory elements implicated in testis-specific transcription are evident, including GATA and GATA-like sites, p53 half-element, ETS binding site, Pu box, PEA3 sequences, MEF-2 motif, and an insulin response element (IRE) site. However, the NOS I transcriptional regulatory regions have not been characterized functionally.

Expressional Regulation of NOS II

Regulation of NOS II Transcription and mRNA Stability

Control of expression seems to be the main regulatory mechanism of NOS II activity. NOS II protein can synthesize NO continuously until the enzyme becomes degraded (Geller and Billiar, 1998; MacMicking *et al.*, 1997). Regulation of the transcription of the NOS II gene is believed to be the most important control mechanism for NOS II expression. The induction level seen in transient transfection experiments using the murine or rat NOS II promoters equals the induction levels seen for the endogenous NOS II mRNA (Kinugawa *et al.*, 1997; Lowenstein *et al.*, 1993; Xie *et al.*, 1993). However, in the human system, there are marked differences between promoter activity and NOS II mRNA. In noninduced AKN hepatocytes, no NOS II mRNA could be detected. Induction with cytokines then resulted in a marked expression of NOS II mRNA. In contrast, nuclear run-on experiments demonstrated a significant basal activity of the human NOS II promoter in AKN and DLD-1 cells that was only enhanced two- to fivefold by cytokine induction (de Vera *et al.*, 1996a; Linn *et al.*, 1997). This paralleled the moderate inducibility seen in transfection experiments with 11-kb or 16-kb human NOS II promoter fragments (de Vera *et al.*, 1996a; Linn *et al.*, 1997; Kleinert, 1999, unpublished results).

These findings suggest that—especially in human cells—regulation of NOS II mRNA stability plays an important role for NOS II induction. Sequence analysis of the human NOS II mRNA (Geller *et al.*, 1993) reveals four sequence motifs (AUUUA) in the 3'-untranslated region (3'-UTR), which have been shown to confer mRNA destabilization to cytokine- and oncogene mRNAs (Caput *et al.*, 1986). The same sequence motifs are found twice in the 3'-UTR of the murine NOS II mRNA (Lyons *et al.*, 1992), and four times in the rat NOS II mRNA (Galea *et al.*, 1994). In murine RAW264.7 macrophages, a cycloheximide-sensitive degradation pathway has been described for NOS II mRNA; the half-life of the IFN- γ -induced mRNA increased from 1–1.5 hours in the

absence of cycloheximide to 4–6 hours in the presence of the inhibitor (Evans *et al.*, 1994). Also the potentiating effect of IFN- γ on LPS-induced NOS II mRNA expression has been attributed to an IFN- γ -mediated stabilization of the NOS II mRNA (Weisz *et al.*, 1994).

In transfection experiments with human A549 or DLD-1 cells, the 3'-UTR of the human NOS II mRNA destabilized the mRNA of a luciferase reporter gene (Rodriguez-Pascual *et al.*, 1999). Also, Nunokawa *et al.* (1997) described an important function of the genomic 3'-flanking sequence of the human NOS II gene for NOS II expression. These authors used luciferase reporter gene constructs containing a human 1.2-kb NOS II promoter in front of luciferase. Behind the luciferase gene they cloned either a 1-kb fragment of human NOS II genomic sequence (composed of the 3'-UTR, the poly-A signal of the human NOS II gene, and 500 bp of the 3'-flanking sequence) or an SV40 poly-A signal. In transient transfection experiments with human A549 cells, the constructs containing the human NOS II 3'-UTR/poly-A/3'-flanking sequence displayed much higher inducibility (11-fold) than those containing only the SV40 poly-A sequence (1.5-fold). These data suggest that the 3'-flanking sequence of the human NOS II gene cooperates with the 5'-flanking promoter sequence in the induction of the human NOS II gene (Nunokawa *et al.*, 1997).

Regulation of NOS II mRNA Translation and Protein Stability

Regulation of the NOS II mRNA translation and protein stability has also been described. Human primary cardiomyocytes express NOS II mRNA, but no NOS II protein in cell culture (Lüss *et al.*, 1997). However, transfection of COS cells with eucaryotic expression vectors containing the human NOS II cDNA (isolated from cardiomyocytes) resulted in NOS II protein expression. Similarly, infection of primary human cardiomyocytes with a retroviral vector containing only the NOS II coding region (no 5'- and 3'-UTR) produced a marked NOS II protein expression. These data suggest that human cardiomyocytes express (protein) factors that inhibit NOS II mRNA translation by interacting with the 5'- and/or 3'-UTR sequences of the NOS II mRNA (Lüss *et al.*, 1997). The inhibition of NOS II expression by different agents, for example, by transforming growth factor- β 1 (TGF- β 1) in primary murine macrophages (Vodovotz *et al.*, 1993) and dexamethasone in rat mesangial cells (Kunz *et al.*, 1996) had been described to result from NOS II mRNA and protein destabilization.

Chu *et al.* (1995) showed that human macrophages and epithelial cells express small amounts (~6%) of cytokine-induced NOS II mRNAs with truncated 5' ends. These minor transcripts seem to result from transcription reactions initiated at different minor start sites. Alternative splicing of the NOS II mRNA had been described resulting in different NOS II mRNA isoforms (Eissa *et al.*, 1998). One mRNA codes for a NOS II protein lacking exons 8 and 9, which are important for NOS II dimerization (Eissa *et al.*, 1998).

Translation and potential function of these NOS II variants remain to be shown.

NOS II Promoter Sequences

The published sequences of the human, murine, and rat NOS II promoters exhibit homologies to numerous binding sites for transcription factors such as AP-1, CCAAT enhancer-binding protein (C/EBP), c-ETS-1, CREB, GATA, (hypoxia-inducible factor (HIF), heat shock factor (HSF), interferon- γ regulatory factor-1 (IRF-1), NF-1, nuclear factor of activated T cells (NFAT), NF- κ B, nuclear factor IL6 (NF-IL6), octamer binding factor-1 (Oct-1), polyomavirus enhancer activator 3 (PEA3), p53, SV40 virus promoter specific transcription protein 1 (Sp1), serum response factor (SRF), and signal transducer and activator of transcription 1 α (STAT1 α) (Chu *et al.*, 1998; Lowenstein *et al.*, 1993; Xie *et al.*, 1993; Zhang *et al.*, 1998) (GenBank AC005697). A comparison of the first 1000 bp of the three mammalian NOS II promoters shows a much greater homology between the rodent promoters (73% identity) than between rodent and human promoters (mouse/human 55%, rat/human 59%). However, with respect to the positions of the putative transcription factor binding sites, all three mammalian promoter sequences are relatively similar (Fig. 1). All three promoters contain a TATA box roughly 30 bp from the transcription start site. Near the TATA box, all three promoters contain

binding sites for the transcription factors NF- κ B, NF-IL6, and octamer factors and for transcription factors induced by tumor necrosis factor- α (TNF- α). At position -900 bp, all three promoters display binding sites for transcription factors induced by IFN- γ [γ -interferon-activated site (GAS), γ -interferon-responsive element (γ IRE), interferon-stimulated regulatory elements (ISRE)]. The murine and rat promoters also contain an NF- κ B site at this position.

In transfection experiments, both rodent 1000-bp NOS II promoter fragments showed full promoter functionality in homologous (Lowenstein *et al.*, 1993; Xie *et al.*, 1993) and heterologous (Kleinert *et al.*, 1996a) cells. In contrast, the human 1000-bp NOS II promoter fragment showed low, but significant basal promoter activity, but no induction with cytokines (Chu *et al.*, 1998; de Vera *et al.*, 1996b; Linn *et al.*, 1997). When the same human promoter fragment was transfected into murine RAW264.7 macrophages, it became markedly inducible with LPS, IFN- γ , and IL-1 β (Kolyada *et al.*, 1996). In human AKN, A549, or DLD-1 cells only NOS II promoter fragments larger than 3.8 kb showed significant induction with cytokines (Chu *et al.*, 1998; de Vera *et al.*, 1996b; Linn *et al.*, 1997). Thus, transcription factor binding sites relevant for cytokine induction of the human NOS II promoter seem to be located upstream of -3.8 kb of the 5'-flanking sequence of the human NOS II gene. Data by de Vera *et al.* (1996b) showed maximal induction (10-fold) with a 16-kb human NOS II promoter fragment. A549/8 cells

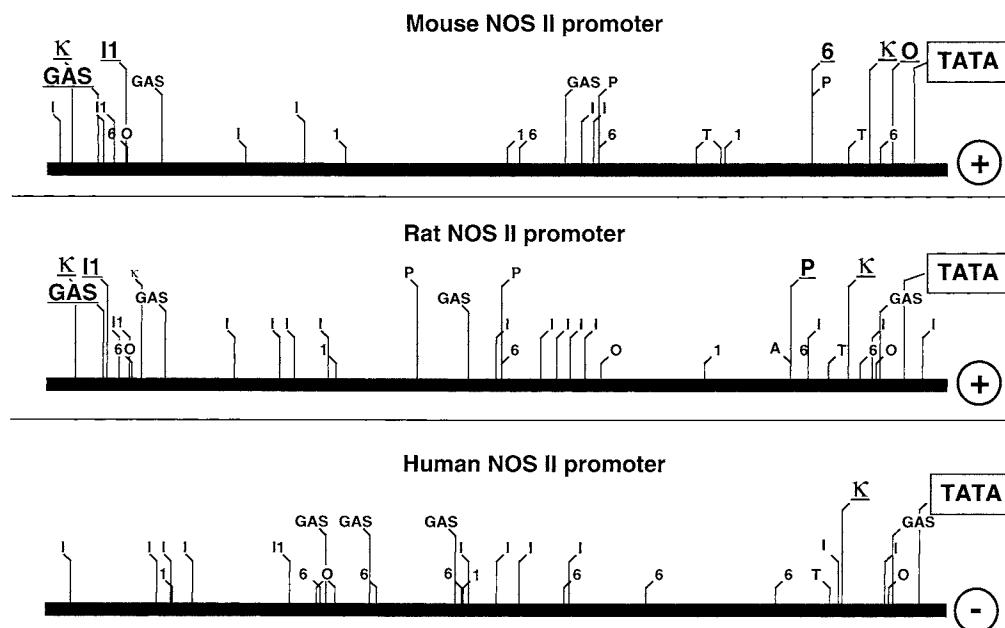

Figure 1 Comparison of the transcription factor binding sites in the first 1000 bp of the murine, rat, and human NOS II promoters (adapted from Kinugawa *et al.*, 1997; Nunokawa *et al.*, 1994; Xie *et al.*, 1993). The figure shows the TATA box (TATA) and putative binding sites for the transcription factors AP-1 (1), C/EBP (P), octamer factors (O), NF- κ B (κ), as well as interleukin-6 (6) and tumor necrosis factor- α (T) response elements. Also shown are the binding sites for interferon- γ -induced transcription factors: γ IRE (I), I1, for the binding of transcription factor IRF-1, and GAS, for the binding of transcription factor STAT-1 α . Large underlined letters indicate an established function of the DNA binding site as demonstrated in transfection or gelshift experiments. In homologous systems, the murine and rat 1000-bp promoter fragments are inducible with cytokines (+), whereas the 1000-bp human promoter fragment is not (-).

stably transfected with this fragment cloned before luciferase showed basal NOS II promoter activity that was enhanced five- to eightfold by cytokines (Kleinert *et al.*, 1999). A construct containing a NOS II promoter fragment ranging from positions -7.2 to -16 kb cloned before a minimal thymidine kinase promoter was still inducible five- to sixfold with cytokines in transiently transfected AKN cells (de Vera *et al.*, 1996b). This suggests that transcription factor binding sites important for the cytokine induction of the human NOS II promoter activity are located upstream of position -7.2 kb. Interestingly, data by another group (Chu *et al.*, 1998; Marks-Konczalik *et al.*, 1998) showed much higher inducibility (up to 50-fold) of a human 8.3-kb NOS II promoter fragment in human A549 cells. The reason of this marked difference in promoter inducibility is not clear at this time.

Signaling Pathways and Transcription Factors Regulating the NOS II Promoter(s)

The regulation of NOS II expression seems to be cell- and species-specific. Analyses of the signal transduction pathways involved in NOS II expression show a marked heterogeneity (Table I). Murine cells generally express NOS II in response to LPS, stimulatory cytokines such as IFN- γ , IL-1 β , IL-6, TNF- α , or other compounds. In contrast, most human cells require a cytokine combination including IFN- γ , IL-1 β , and TNF- α for NOS II induction (Geller and Billiar, 1998). In addition, many compounds have been described that enhance (Table II) or inhibit (Table III) LPS/cytokine-induced NOS II expression in different cells and tissues.

TRANSCRIPTION FACTOR NF- κ B

The transcription factor NF- κ B (Ghosh *et al.*, 1998) seems to be a central target for activators or inhibitors of NOS II expression. LPS, IL-1 β , TNF- α , and oxidative stress for instance have been shown to induce NOS II expression in different cell types by activating NF- κ B. Also, inhibition of NOS II expression by glucocorticoids, TGF- β 1, antioxidants like pyrrolidine dithiocarbamate (PDTC), and inhibitors of phosphatidyl choline-specific phospholipase C (PC-PLC) have been shown to result from inhibition of NF- κ B activation. This inhibition may result from direct inhibition of NF- κ B (by protein-protein interactions) (Kleinert *et al.*, 1996a; Mukaida *et al.*, 1994) or from enhancement of the expression of I- κ B, the specific inhibitor of NF- κ B (de Vera *et al.*, 1997). Analyses using murine (Goldring *et al.*, 1996; Lowenstein *et al.*, 1993; Xie *et al.*, 1994), rat (Eberhardt *et al.*, 1998; Spink *et al.*, 1995), and human (Marks-Konczalik *et al.*, 1998; Taylor *et al.*, 1998b) cells showed the important role of NF- κ B binding sites for the induction of the NOS II promoter activity. In the murine NOS II promoter, the downstream NF- κ B binding site (positions -76 to -85 bp) seems to be the most important one (Xie *et al.*, 1994), but the upstream NF- κ B site (positions -974 to -960 bp) also seems to have some functionality and cooperativeness with the downstream site (Murphy *et al.*, 1996;

Spink *et al.*, 1995). For the NF- κ B binding sites in the human NOS II promoter, conflicting results have been published. Taylor *et al.* (1998b) reported interactions of multiple NF- κ B binding sites between positions -5.2 and -6.5 kb in the induction of the NOS II promoter. In contrast, these authors attributed little functionality to the downstream NF- κ B site of the human NOS II promoter (positions -115 to -106 bp, near the TATA box). Other groups, however, reported on the importance of this downstream NF- κ B binding site for human NOS II promoter activity (Marks-Konczalik *et al.*, 1998; Nunokawa *et al.*, 1996; Sakitani *et al.*, 1998).

OCTAMER FACTOR-BINDING SITE

Recent data demonstrated an important function of an octamer factor-binding site (positions -54 to -62 bp) for murine NOS II promoter activity stimulated by LPS (Kim *et al.*, 1999; Pellacani *et al.*, 1999; Perrella *et al.*, 1999; Xie, 1997). Incubation of murine M1-macrophages with IL-6 induced the binding of transcription factors to this octamer site. Mutation of the octamer sequence inhibited IL-6-induced NOS II promoter activity (Sawada *et al.*, 1997). *In vivo* footprinting assays also showed binding of transcription factors to this octamer sequence (Goldring *et al.*, 1996). This octamer-binding site may be the target for the transcription factor family members Oct-1, Oct-2, Brn [brain-specific transcription factors of the POU (transcription factors containing protein sequences homologous to the mammalian Pit-1, Oct-1, Oct-2, and *Caenorhabditis elegans* Unc-86 gene products) family]-3a, and Brn-3b (Gay *et al.*, 1998; Kim *et al.*, 1999). However, binding of members of the high mobility group-I(Y) protein family of transcription factors has also been suggested (Pellacani *et al.*, 1999; Perrella *et al.*, 1999).

BINDING SITE FOR TRANSCRIPTION FACTOR IRF-1

In murine RAW264.7 macrophages, the essential role of the IRF-1 binding site (positions -913 to -923 bp) for the induction of the murine NOS II promoter has been shown. Mutations of this binding site blocked the IFN- γ -mediated enhancement of the LPS-induced NOS II promoter activity in macrophages (Martin *et al.*, 1994; Spink and Evans, 1997). Supershift experiments showed the involvement of IRF-1 in the protein complexes bound to this binding site after IFN- γ incubation (Martin *et al.*, 1994). *In vivo* footprint experiments with LPS-incubated RAW264.7 macrophages supported this data (Goldring *et al.*, 1996). Also, nuclear extracts from rat cardiomyocytes incubated with LPS and IFN- γ contained proteins binding to the homologous ISRE on the rat NOS II promoter (Kinugawa *et al.*, 1997). The inhibitory effect of IL-4 on IFN- γ -stimulated NOS II expression in murine macrophages has been attributed to the IL-4-induced potentiation of IFN- γ -induced IRF-2 expression. Because IRF-2 competes with IRF-1 for ISRE binding (Yamamoto *et al.*, 1994), the reduced NOS II expression may result from a reduced IRF-1 binding to the ISRE on the murine NOS II promoter (Paludan *et al.*, 1999). Finally, in macrophages and glial cells from IRF-1 $^{-/-}$ mice, LPS/IFN- γ incubation resulted in markedly reduced NOS II ex-

pression (Fujimura *et al.*, 1997; Kamijo *et al.*, 1994; Shiraishi *et al.*, 1997).

BINDING SITE FOR TRANSCRIPTION FACTOR STAT1α

In addition to IRF-1 binding sites, all mammalian NOS II promoters contain several homologies to STAT1α binding sites (GAS). Gao *et al.* (1997) reported that binding of STAT1α to the GAS of the murine NOS II promoter (positions -934 to -942 bp) is required for optimal induction of the NOS II gene by IFN-γ and LPS. Also the IFN-γ-mediated enhancement of IL-1β-induced promoter activity in rat RINm5F cells was dependent on the GAS and ISRE sites around position -900 bp of the rat NOS II promoter (Darville and Eizirik, 1998). Furthermore, incubation of rat cardiomyocytes with LPS or cytokines induced proteins with

DNA binding activity for oligonucleotides containing the homologous rat GAS sequence (Kinugawa *et al.*, 1997). In contrast to macrophages, chondrocytes and hepatocytes from IRF-1^{-/-} mice showed normal NOS II induction in response to LPS/IFN-γ (Shiraishi *et al.*, 1997). In these cell types, IRF-1 does not seem to be essential for NOS II induction. These data underline the cell specificity of the regulation of NOS II expression. Induction of IRF-1 activity by IFN-γ depends on protein *de novo* synthesis and on STAT1α activation (Boehm *et al.*, 1997). Induction of IRF-1 expression precedes IFN-γ-mediated potentiation of IL-1β-induced NO production in rat RINm5F cells (Flodstrom and Eizirik, 1997). Therefore, STAT1α is likely to be involved in the stimulation of NOS II induction, either directly by binding to the NOS II promoter, or indirectly by inducing IRF-1

activity. In addition, positive cooperativeness between STAT1 α and IRF-1 is likely to occur for the induction of the NOS II promoter (Darville and Eizirik, 1998). Furthermore, NOS II induction was blocked in macrophages from mice with a disrupted STAT1 α gene (Meraz *et al.*, 1996). In human DLD-1 cells, inhibition of the IFN- γ -activated tyrosine kinase JAK2 (janus kinase 2) by tyrphostin B42 (AG 490) reduced STAT1 α DNA-binding activity and NOS II expression (Kleinert *et al.*, 1998a).

CAMP-INDUCED TRANSCRIPTION FACTORS

In murine 3T3 fibroblasts, the induction of NOS II mRNA by cyclic AMP-elevating agents such as forskolin and 8-bromo-cAMP is mediated by the activation of transcription factor NF- κ B (Kleinert *et al.*, 1996b). However, induction of NOS II expression in rat mesangial cells by cAMP-elevating compounds is not inhibited by inhibitors of NF- κ B activation (Eberhardt *et al.*, 1994). Therefore, in these cells, the cAMP-mediated induction may depend on cAMP-induced transcription factors (CREB, C/EBP) (Eberhardt *et al.*, 1998; Kinugawa *et al.*, 1997). Eberhardt *et al.* (1998) reported

that a CCAAT box (C/EBP binding site, positions -155 to -163 bp) is essential for cAMP-mediated (but not IL-1 β -mediated) induction of the rat NOS II promoter. Supershift experiments showed the involvement of C/EBP β and C/EBP δ in the cAMP regulation of the rat NOS II promoter. In a heterologous transfection system using primary rat hepatocytes and fragments of the human NOS II promoter, Sakitani *et al.* (1998) showed inducibility of a human NOS II promoter fragment corresponding to the sequence from position -365 bp to the start site. When a C/EBP-binding site (or an NF- κ B binding site) within this region was mutated, promoter activity was markedly reduced. Gelshift/supershift experiments demonstrated the existence of C/EBP β in the DNA-protein complexes which may stimulate NOS II gene expression synergistically with NF- κ B in rat hepatocytes (Sakitani *et al.*, 1998).

TRANSCRIPTION FACTOR HIF-1

In transient transfection experiments using murine macrophages and bovine pulmonary endothelial cells, the hypoxia-mediated induction of the murine NOS II promoter

has been shown to be regulated by the transcription factor HIF-1 (Melillo *et al.*, 1995, 1996; Palmer *et al.*, 1998). Site-directed mutation of the HIF-1 binding site (positions –212 to –226 bp) blocked hypoxia-mediated induction of the murine NOS II promoter. Nuclear extracts from hypoxia-treated cells contained high levels of DNA-binding activity specific for the HIF-1 site of the murine NOS II promoter. Supershift experiments showed the presence of HIF-1 in the DNA–protein complexes (Palmer *et al.*, 1998). Also the induction of the NOS II promoter activity by picolinic acid and desferrioxamine seems to depend on the HIF-1 binding site (Melillo *et al.*, 1995, 1997).

TRANSCRIPTION FACTOR AP-1

The role of the transcription factor AP-1 in the regulation of NOS II expression is controversial. In RAW264.7 macrophages, a truncated fragment of the murine NOS II promoter lacking the upstream AP-1 binding site (at position –1125 bp) exhibited slightly higher promoter activity than a longer promoter fragment including this binding site (Lowenstein *et al.*, 1993). In human DLD-1- and A549/8 cells, overexpression of AP-1 by cotransfection of c-jun and c-fos expression vectors inhibited the promoter activity of a 7-kb human NOS II promoter fragment (Kleinert *et al.*, 1998a). Similarly, agents such as calyculin A, ocadaic acid, phenylarsine oxide, and anisomycin, which markedly enhance c-jun and c-fos mRNA expression and AP-1 binding activity, inhibited cytokine-induced NOS II expression in human DLD-1- and A549/8 cells (Kleinert *et al.*, 1998a, 1999). In stably transfected A549/8 cells containing a 16-kb NOS II promoter-luciferase reporter gene construct, all of these compounds also reduced the cytokine-induced NOS II promoter activity (Kleinert *et al.*, 1999). In contrast, Marks-Konczalik *et al.* (1998) described a marked inhibition (90%) of cytokine-induced activity of an 8.3-kb NOS II promoter fragment transfected into A549 cells after site-directed mutagenesis of an AP-1 binding sequence located 5301 bp upstream of the transcription start site. Site-directed mutagenesis of another AP-1 site located 5115 bp upstream of the transcription start site reduced NOS II promoter activity by 45%. In supershift experiments, these authors detected Jun D and Fra-2 as components of the cytokine-induced AP-1–DNA–protein complexes (Marks-Konczalik *et al.*, 1998). The discrepancies between these findings may result from different AP-1 expression levels. The marked overexpression of AP-1 induced by calyculin A, ocadaic acid, phenylarsine oxide, and anisomycin may result in squelching of transcription cofactors such as CBP/p300 which may be essential for STAT1 α - or NF- κ B-mediated transcription.

TUMOR SUPPRESSOR p53

Overexpression of the tumor suppressor p53 inhibited the activity of the human NOS II promoter (Forrester *et al.*, 1996), and mice with a disrupted p53 gene showed a higher NOS II expression than wild-type mice (Ambs *et al.*, 1998b).

Expressional Regulation of NOS III

Shear Stress

Shear stress produced in blood vessels by the flowing blood upregulates NOS III expression (Nishida *et al.*, 1992; Sessa *et al.*, 1994; Xiao *et al.*, 1997) (Table IV). The enhancement of NOS III mRNA expression in bovine aortic endothelial cells (BAEC) by shear stress was not inhibited by dexamethasone, inhibitors of tyrosine kinases, or inhibition of G-protein signaling. In contrast, chelation of intracellular calcium in BAEC reduced shear stress induction of NOS III mRNA by almost 70% (Xiao *et al.*, 1997). Pertussis toxin also inhibited the shear-induced increase in NOS III mRNA, implicating a pertussis toxin-sensitive G-protein in this response (Malek *et al.*, 1999). Shear-induced upregulation of NOS III mRNA was potentiated by the PI (phosphatidylinositol) 3-kinase inhibitors wortmannin and LY294002, suggesting that PI 3-kinase inhibits the shear response (Malek *et al.*, 1999). A putative shear stress-responsive element (6-bp core sequence 5'-GAGACC-3') has been described in the promoter sequence of the human and bovine NOS III gene (see below) (Marsden *et al.*, 1993; Venema *et al.*, 1994). However, the functionality of this element has not been proven. In BAEC, shear responsiveness was conferred on a luciferase reporter gene by a portion of the bovine NOS III gene promoter (positions –779 to –1600 bp) (Malek *et al.*, 1999).

Oxygen Tension and Hypoxia

Hypoxia has been shown consistently to downregulate NOS III expression. In human primary pulmonary artery endothelial cells (Ziesche *et al.*, 1996), cultured porcine pulmonary artery endothelial cells (Dai *et al.*, 1995), and bovine pulmonary artery endothelial cells (Liao *et al.*, 1995b), hypoxia reduced NOS III mRNA and/or protein. At least in the bovine species this was attributed to both a decreased rate of transcription and a destabilization of the NOS III mRNA (Liao *et al.*, 1995b). The downregulation of NOS III may be implicated in pulmonary ventilation–perfusion coupling (with poorly ventilated areas of the lung being poorly perfused).

In nonpulmonary endothelial cells, the findings are more controversial. In BAEC, Arnet *et al.* (1996) saw an upregulation of NOS III mRNA and protein expression in cells incubated at low oxygen tension (1%). In this study, hypoxia did not change the stability of NOS III mRNA. On the other hand, the promoter activity of a 1.6-kb DNA fragment of the 5'-flanking sequence of the human NOS III gene was enhanced by hypoxia (Arnet *et al.*, 1996). Therefore, enhanced NOS III expression in response to hypoxia is likely to result from enhanced promoter activity (Arnet *et al.*, 1996). However, the human NOS III promoter contains no homology to the published binding sequence of the hypoxia-induced transcription factor HIF. Zhang *et al.* (1993) reported upregulation of endothelial NOS III immunoreactivity in cerebral

blood vessels during cerebral ischemia. Other reports, however, demonstrated reductions of NOS III expression in human umbilical vein endothelial cells (HUVEC) and BAEC exposed to low oxygen tension (McQuillan *et al.*, 1994; Phelan and Faller 1996) (Table IV). This reduction in NOS III expression was reported to result from decreased stability of NOS III mRNA and reduced NOS III promoter activity (McQuillan *et al.*, 1994).

Proliferation and Growth Status

It has been shown that NOS III mRNA and protein is increased in growing versus resting BAEC (Arnal *et al.*, 1994) (Table IV). This enhanced NOS III expression was found to be the result of a greater stability of the NOS III mRNA in proliferating compared with confluent BAEC (Arnal *et al.*, 1994). Growth-arrested BAEC showed enhanced expression of a protein that interacts with the 3'-UTR of the bovine NOS III mRNA and destabilized the mRNA (Harrison, 1997). In contrast to the above results, Flowers *et al.* (1995) reported a reduction of NOS III mRNA and protein in asynchronously proliferating cultures and wounded endothelial cell monolayers compared with quiescent nonproliferating cells (Table IV). Because run-on experiments showed no change in transcription rates, the reduction of NOS III mRNA in proliferating cells was attributed to NOS III mRNA destabilization (Flowers *et al.*, 1995). The reason for these discrepant findings between the two groups is not clear at this time.

Cytokines and Bacterial LPS

TNF- α downregulates NOS III mRNA, protein, and activity in BAEC and HUVEC (Lamas *et al.*, 1992; Nishida *et al.*, 1992). The downregulation of NOS III mRNA expression by TNF- α in HUVEC has been ascribed to a destabilization of NOS III mRNA with no effect on transcription (Yoshizumi *et al.*, 1993). In bovine endothelial cells, this destabilization seems to result from a specific interaction of a TNF- α -induced protein with the 3'-UTR-sequence of the NOS III mRNA (Alonso *et al.*, 1997). In contrast, in resident astrocytes of the central nervous system, Barna *et al.* (1996) described an enhancement of NOS III immunoreactivity when mice were treated intraperitoneally with IL-12, a potent activator of IFN- γ and TNF- α production. These authors also found a cytokine-mediated activation of NOS III expression following exposure of C6 glioma cells to IL-12, IFN- γ , and TNF- α (Barna *et al.*, 1996). C6 glioma cells express NOS III constitutively. Kaku *et al.* (1997) described an upregulation of NOS III mRNA expression and NOS III promoter activity by treatment of BAEC with IFN- α/β and LPS. Similarly, Bucher *et al.* (1997) found an upregulation of NOS III mRNA expression in the liver of LPS- or lipoteichoic acid-treated rats. They concluded that NOS III might be an even more important source of NO than NOS II in the liver after stimulation with LPS or lipoteichoic acid (Bucher

et al., 1997). In contrast, LPS injection into rats has been shown to reduce NOS III mRNA expression (along with NOS I mRNA expression) in aorta, heart, and lung (Liu *et al.*, 1996). Another study demonstrated a downregulation of NOS III in gastrointestinal mucosa following LPS treatment of rats (Chen *et al.*, 1997). Therefore, cytokines and LPS seem to regulate NOS III expression in different ways depending on the cytokine combination, the species, and the cell type analyzed.

Estrogens and Other Sex Steroids

Both pregnancy and estradiol treatment enhanced NOS III mRNA (along with NOS I mRNA) in guinea pig skeletal muscle (Weiner *et al.*, 1994b). An increase in NOS III mRNA has also been seen in the aortae of pregnant or estrogen-treated, but not progesterone- or testosterone-treated, rats (Goetz *et al.*, 1994). Also, the kidneys from female rats contained more NOS III protein than those of male or oophorectomized female rats (Neugarten *et al.*, 1997). Estrogen replacement therapy increased medullary NOS III levels in oophorectomized animals (Neugarten *et al.*, 1997). On the other hand, in *in vitro* studies with ovine fetal pulmonary artery endothelial cells, estrogens enhanced NOS III activity but did not affect NOS III mRNA expression (Lantin-Hermoso *et al.*, 1997). A study on bovine endothelial cells claimed that 17 α -ethinyl estradiol did not enhance the expression of NOS III but increased the release of bioactive NO by inhibiting superoxide anion production (Arnal *et al.*, 1996). Studies performed in our own laboratory (Kleinert *et al.*, 1998b) demonstrated that estrogens did enhance NOS III mRNA and protein expression in EA.hy 926 human endothelial cells. The increased NOS III expression resulted from an increased NOS III promoter activity with unchanged mRNA stability. In the absence of a bona fide estrogen responsive element in the human NOS III promoter (see below), the increased NOS III promoter activity may result from an enhanced binding activity of transcription factor Sp1 (which is essential for the human NOS III promoter, see below) (Kleinert *et al.*, 1998b).

Growth Factors

Recent evidence indicates that an incubation of endothelial cells with certain growth factors may upregulate NOS III expression. Incubation of BAEC with TGF- β 1 produced a modest upregulation of NOS III mRNA and protein (Inoue *et al.*, 1995). This upregulation of NOS III was reported to result from enhanced promoter activity. Deletion of a putative NF-1 binding site in the bovine NOS III promoter abolished the TGF- β 1-enhanced promoter activity (Inoue *et al.*, 1995). Similarly, incubation of BAEC with basic fibroblast growth factor enhanced NOS III mRNA, protein, and activity (Kostyk *et al.*, 1995). In addition, vascular endothelial growth factor had been described to upregulate NOS III

Table IV Conditions or Compounds That Modify NOS III Expression

Condition or compound	Cell, tissue	Species	Regulation	Method of detection	References
Shear stress	Aortic endothelial cells	Bovine, porcine	Upregulation	Northern blot	Nishida <i>et al.</i> (1992); Woodman <i>et al.</i> (1999)

^aDiscrepant findings in nonpulmonary endothelial cells; both upregulation (Arnet *et al.*, 1996; Zhang *et al.*, 1993) and downregulation (McQuillan *et al.*, 1994; Phelan and Faller, 1996) of NOS III have been reported.

^bDiscrepant findings; both upregulation (Arnal *et al.*, 1994) and downregulation (Flowers *et al.*, 1995) of NOS III have been reported.

^cThe NOS III upregulation has not been seen in some other models (Arnal *et al.*, 1996; Lantin-Hermoso *et al.*, 1997).

^dCausing downregulation (Ohara *et al.*, 1995) or stimulation (Li *et al.*, 1998) of protein kinase C.

expression in HUVEC (Hood *et al.*, 1998; Kroll and Waltenberger, 1998).

Oxidized Low-Density Lipoproteins and Lysophosphatidylcholine

The effects of oxidized low-density lipoprotein (ox-LDL) on NOS III expression are complex. In human saphenous vein endothelial cells, ox-LDL (50 $\mu\text{g/ml}$) has been reported to reduce NOS III mRNA levels by decreasing the half-life of the mRNA (Liao *et al.*, 1995a). The effect of ox-LDL (50 $\mu\text{g/ml}$) on NOS III promoter activity was biphasic as measured in nuclear run-on experiments. Treatment with ox-LDL decreased NOS III promoter activity by about 25% in the first 6 hours followed by 1.8- and 2.2-fold increases at 12 and 24 hours, respectively (Liao *et al.*, 1995a) (Table IV). Hirata *et al.* (1995) found an upregulation of NOS III mRNA in BAEC incubated with low concentrations of ox-LDL (10 $\mu\text{g/ml}$), whereas high concentrations (100 $\mu\text{g/ml}$) reduced mRNA levels after 24 hours. Similar responses were seen with lysophosphatidylcholine, another component of atherogenic lipoprotein (Table IV). In HUVEC, lysophosphatidylcholine upregulated NOS III expression (Zembowicz *et al.*, 1995) (Table IV). Using nuclear run-on assays and reporter gene analyses, this enhanced NOS III expression was shown to result from lysophosphatidylcholine-stimulated NOS III promoter activity (Wu *et al.*, 1997).

Modulation of Protein Kinase C Activity

Incubation of BAEC (Ohara *et al.*, 1995) or human EA.hy 926 endothelial cells (Li *et al.*, 1998) with phorbol esters enhanced NOS III expression. Ohara *et al.* (1995) concluded from their results that downregulation of protein kinase C (PKC) by long-term incubation with phorbol esters (or PKC inhibition with staurosporine) enhances NOS III expression. In contrast to these results, in our own experiments with human EA.hy 926 endothelial cells, the time course of phorbol ester-induced enhancement of NOS III expression paralleled PKC activation rather than inhibition (Li *et al.*, 1998) (Table IV). Also, specific PKC inhibitors such as bisindolylmaleimide I, Gö 6976, Ro-31-8220, and chelerythrine prevented the phorbol ester-induced enhancement of NOS III expression. Based on transfection experiments with a 3.5-kb human NOS III promoter fragment, the phorbol ester-stimulated enhancement of NOS III expression seems to be a transcriptional event (Li *et al.*, 1998). Additional conditions and compounds that have been described to up- or downregulate NOS III expression are summarized in Table IV.

Characterization of the 5'-Flanking Sequences of the NOS III Gene

Analyses of the 5'-flanking region of human NOS III demonstrated that the promoter is "TATA-less." It exhibits

proximal promoter elements consistent with a constitutively expressed gene such as Sp1 and GATA motifs (Karantzoulis-Fegaras *et al.*, 1999; Zhang *et al.*, 1995) (Fig. 2). Furthermore, the human NOS III promoter contains consensus sequences for the binding of the transcription factors AP-1, AP-2, ETS, myc-associated zinc finger protein (MAZ), NF-1, NF-IL6, NF- κ B, PEA3, and Ying Yang (YY1), as well as CACCC-, CCAAT-, heavy metal-, acute-phase response-, shear stress-, cAMP-response-, retinoblastoma control-, IFN- γ -response-, and sterol-regulatory *cis* elements (Fig. 2). The promoter sequence also contains several half sites of the estrogen-responsive element (ERE). However, no bona fide EREs are found (Fig. 2). A functional relevance has been demonstrated for only a few of these potential binding sites. Deletion and mutation analyses revealed an essential role of the Sp1 binding site at position -103 bp (Zhang *et al.*, 1995). Also, the stimulation of the human NOS III promoter by estrogens in human EA.hy 926 endothelial cells (Kleinert *et al.*, 1998b) and by lysophosphatidylcholine in HUVEC (Wu *et al.*, 1997) may result from an enhanced binding activity of transcription factor Sp1. Mutation of the consensus GATA site at position -230 bp reduced human NOS III promoter activity by about 30% (Zhang *et al.*, 1995). Mutation of the PEA3 binding site at position -26 bp reduced promoter activity by about 50% (Wu *et al.*, 1997). Linker scanning mutation, competitive gelshift, and cotransfection analyses showed involvement of the transcription factors Elf-1, Ets-1, MAZ, Sp3, and YY1 in the regulation of human NOS III promoter activity (Karantzoulis-Fegaras *et al.*, 1999). These transcription factors bind to two tightly clustered regions (positions -95 to -104 bp and -115 to -144 bp) of the human NOS III promoter. Elf-1, Ets-1, Sp3, and YY1 seem to positively regulate human NOS III promoter activity, whereas MAZ seems to inhibit the NOS III promoter (Karantzoulis-Fegaras *et al.*, 1999). Arnet *et al.* (1996) demonstrated an enhanced activity of the human NOS III promoter in transfected bovine endothelial cells exposed to hypoxia. However, the human NOS III promoter contains no homology to a HIF-1 consensus sequence, and none of the other consensus sequences described above are known to mediate induction of promoter activity by hypoxia. Phorbol ester incubation of human endothelial cells transfected with a human NOS III promoter-luciferase construct produced an enhancement of promoter activity (Li *et al.*, 1998). However, the transcription factors involved are not yet known.

The published 2.9-kb 5'-flanking sequence of the bovine gene (Venema *et al.*, 1994) and the 1.8-kb 5'-flanking sequence of the murine gene (Teichert *et al.*, 1998) lack a typical "TATA box" and contain mostly the same transcription factor binding sites as the human NOS III promoter (Fig. 2). In reporter gene assays, a bovine promoter fragment (positions -1548 to +240 bp) showed significant basal activity in transfected BAEC. Interestingly, a deletion fragment (positions -1548 to +192 bp) lacking two putative Sp1 binding sites in the 5'-UTR of the NOS III cDNA lost almost all of its promoter activity, suggesting that transcrip-

Figure 2 Comparison of the transcription factor binding sites of the human, bovine, and murine NOS III promoters (adapted from Miyahara *et al.*, 1994; Teichert *et al.*, 1998; Zhang *et al.*, 1995). The figure shows putative binding sites for the transcription factors AP-1 (1), Ets-1 (E1), GATA (G), IRF-1 (I1), MAZ (M), NF-1 (N), NF- κ B (κ), PEA3 (P3), Sp1 (S), STAT-1 α (GAS), YY1 (Y), as well as shear stress responsive elements (SH) and ERE half-sites (e). Large underlined letters indicate an established function of the DNA binding site as demonstrated in transfection or gelshift experiments. 5'-UTR, 5'-untranslated region of the mRNA; cds, coding sequence.

tion factor Sp1 is important for NOS III gene transcription in the bovine species as well. The modest upregulation of NOS III mRNA by TGF- β 1 in BAEC is likely to be the result of enhanced activity of the bovine NOS III promoter based on increased binding of transcription factor NF-1 to its response element (Inoue *et al.*, 1995). Transfection of BAEC with a β -galactosidase reporter gene construct containing 5.2 kb of the 5'-flanking sequence of the murine

NOS III gene showed significant promoter activity (Teichert *et al.*, 1998).

Acknowledgments

Research in the authors' laboratory pertaining to this topic was supported by the Collaborative Research Center SFB 553, Project A1 (to U.F.), and by Grant K1 1020/4-1 (to H.K.) from the Deutsche Forschungsgemeinschaft.

Molecular Regulation of Inducible Nitric Oxide Synthase

Raymond W. Ganster and David A. Geller

*University of Pittsburgh
Falk Clinic
Pittsburgh, Pennsylvania*

THE GENE FOR INDUCIBLE NITRIC OXIDE SYNTHASE GENE (iNOS) IS EXPRESSED BY MANY SPECIES AND IN A LARGE VARIETY OF CELL TYPES. TYPICALLY, THE EXPRESSION OF iNOS IS REPRESSED IN RESTING CELLS, REQUIRING ACTIVATION BY AN EXPANDING NUMBER OF BIOLOGICAL, CHEMICAL, OR PHYSICAL STIMULI. THE MOLECULAR REGULATION OF iNOS EXPRESSION IS COMPLEX AND OCCURS AT MULTIPLE SITES IN THE GENE EXPRESSION PATHWAY, WITH BOTH TRANSCRIPTIONAL AND POSTTRANSCRIPTIONAL CONTROL MECHANISMS. INDUCTION OF NITRIC OXIDE SYNTHESIS HAS BEEN SHOWN TO ELICIT EITHER BENEFICIAL OR DETRIMENTAL CONSEQUENCES DEPENDING ON THE PHYSIOLOGICAL OR PATHOPHYSIOLOGICAL CONDITION. THEREFORE, UNDERSTANDING THE SIGNALING PATHWAYS AND MOLECULAR MECHANISMS THAT REGULATE iNOS EXPRESSION IS CRITICAL FOR THE DEVELOPMENT OF EFFECTIVE THERAPIES TO MODULATE iNOS EXPRESSION IN DISEASE STATES. THE GOAL OF THIS CHAPTER IS TO SUMMARIZE THE MOLECULAR MECHANISMS THAT GOVERN iNOS GENE EXPRESSION, FOCUSING ON THE REGULATION OF iNOS TRANSCRIPTION. THE MAJOR DIFFERENCES BETWEEN HUMAN AND RODENT iNOS GENE REGULATION WILL BE HIGHLIGHTED AS WELL AS THE MECHANISMS THAT DOWNREGULATE iNOS EXPRESSION.

Introduction

Since the initial discovery that endothelium-derived relaxing factor (EDRF) is nitric oxide gas (NO) (Ignarro *et al.*, 1987), a great deal of scientific effort has been focused on elucidating the mechanisms that regulate nitric oxide synthesis and on understanding the physiological and pathophysiological consequences of biological NO production. Within cells, NO is produced from L-arginine by a family of NOS enzymes. The enzymes are the products of three distinct mammalian genes that are expressed in various cells and tissues. The three NOS genes and encoded proteins are subject to complex positive and negative regulatory inputs that determine the amount and duration of NO production. Table I summarizes the basic genetic organization of the human NOS genes with cell type-specific expression, chromo-

somal location, gene size, and exon–intron structure. The same organization is essentially apparent in the mouse, where chromosomal synteny and sequence homologies indicate that an evolutionarily conserved NOS gene family exists in vertebrates. This chapter will focus on the molecular regulation of the inducible NO synthase (iNOS, NOS2) gene.

The first NOS cDNA, cloned in 1991 by Bredt and Snyder from rat cerebellum, possessed sequence homology with the “characterized” cytochrome P-450 reductase. This knowledge provided important insight into the enzymology and cofactor requirements for NO synthesis (Bredt *et al.*, 1991). Subsequently, human brain nitric oxide synthase was cloned and observed to be expressed constitutively in both neuronal cells and skeletal muscle (Nakane *et al.*, 1993). The activity of the neuronal NOS (nNOS) enzyme is regulated

Table I Gene Structure and Chromosomal Localization of the Human NO Synthase Genes

Human NOS gene	Cell types	Chromosome	Gene size	Gene structure
Constitutive NOS, neuronal type (ncNOS, nNOS, NOS-I, NOS1)	Neuronal cells, skeletal muscle cells, cardiac muscle	12	160kb	29 exons, 28 introns
Constitutive NOS, endothelial type (ecNOS, eNOS, NOS-III, NOS3)	Endothelial cells	7	21 kb	26 exons, 25 introns
Inducible NOS (iNOS, NOS-II, NOS2)	Many cell types	17	37 kb	26 exons, 25 introns

by a calcium-dependent interaction of calmodulin with nNOS, leading to synthesis of NO. The physiological importance of nNOS-derived NO as a signaling molecule with functions in the nervous system is well established (see Section III, NO and the Nervous System, in this book). Another distinct NOS isoform, endothelial NOS or (eNOS), was originally cloned from bovine and human endothelium (Janssens *et al.*, 1992; Lamas *et al.*, 1992; Marsden *et al.*, 1992; Nishida *et al.*, 1992; Sessa *et al.*, 1992). The expression of the eNOS gene is generally constitutive within endothelial cells and is regulated similarly to nNOS. As a result of the calcium dependency for nNOS and eNOS activity, the production of NO by these enzymes is generally transient, resulting in the production of small amounts of NO, which have been called NO puffs. The importance of the eNOS-derived NO in normal physiology is well established. NO produced by mammals was originally identified as the EDRF and regulates normal vascular tone (Ignarro *et al.*, 1987; Vallance *et al.*, 1989).

Cloning of the Murine and Human iNOS Genes

In contrast to the constitutive expression and predominant posttranslational regulation of nNOS and eNOS enzymatic activity, the existence of a bacterial lipopolysaccharide (LPS)- or cytokine-inducible NOS (iNOS) was initially described in mouse macrophage (Stuehr and Marletta, 1985, 1987). The murine iNOS cDNA was subsequently cloned from LPS and γ -interferon (IFN γ)-stimulated macrophages by three independent investigators (Lowenstein *et al.*, 1992; Lyons *et al.*, 1992; Xie *et al.*, 1992). The iNOS gene is typically not expressed in normal resting cells, but on exposure to infectious agents, microbial products, or cytokines, the expression of the iNOS gene is induced, resulting in a sustained, high-output production of NO (see Fig. 1). In contrast to the nNOS and eNOS enzymes, the production of NO by iNOS occurs in the absence of calcium signaling (Cho *et al.*, 1992). Although the dogma remains in place that NO production is regulated primarily by “constitutive” expression of neuronal or endothelial constitutive NOS (cNOS), or by “inducible” expression of iNOS, exceptions to the paradigm exist. For example, iNOS has been shown to be constitutively expressed in certain tissues (Guo *et al.*, 1995;

Hoffman *et al.*, 1997; Mannick *et al.*, 1994). Additionally, although the cNOS protein is constitutively expressed in endothelial cells, full cNOS enzyme activity may depend on cytokine induction of GTP cyclohydrolase I to provide the essential NOS cofactor, tetrahydrobiopterin (Werner-Felmayer *et al.*, 1993). For a review of the expressional control of the cNOS isoforms, see Förstermann *et al.* (1998).

The existence of a human iNOS was initially implied by the increased levels of circulating nitrogen oxides in patients receiving cytokine-based tumor immunotherapy (Hibbs *et al.*, 1992; Ochoa, 1991a) and in trauma or bacterial sepsis (Ochoa *et al.*, 1991b). However, in contrast to murine macrophages, it was difficult to demonstrate that human macrophages expressed an LPS- or cytokine-inducible iNOS (Bertholet *et al.*, 1999). Human iNOS expression in a specific cell type was identified by Nussler in 1992 in primary human hepatocytes stimulated with a cytokine mixture (CM) of LPS, tumor necrosis factor (TNF α), interleukin 1 β (IL-1 β), and IFN γ (Nussler *et al.*, 1992). This then allowed our group to clone the first human iNOS cDNA from LPS- and

Figure 1 A simplified diagram representing the molecular pathways involved in the synthesis of nitric oxide by iNOS. The cytokines TNF α , IL-1 β , IFN γ , and bacterial LPS are inducers of iNOS expression. On engagement of cell surface receptors, a signal transduction cascade is initiated, resulting in the activation of latent, cytoplasmic transcription factors. Activated transcription factors enter the nucleus, bind to promoter DNA sequences in the vicinity of target genes (i.e., iNOS), and activate the transcription of iNOS mRNA. The iNOS mRNA is then processed and translated into protein in the cytoplasm. Cytoplasmic iNOS protein requires a variety of cofactors for enzymatic activity. The guanidino nitrogen of the amino acid arginine is oxidized and cleaved, releasing NO and citrulline as end products of iNOS enzymatic activity. Although any point along this simplified biosynthetic pathway might constitute a limiting or regulatory step in the synthesis of NO by iNOS, it is clear that the predominant mode of regulating NO synthesis by iNOS occurs at the level of iNOS mRNA transcription.

cytokine-stimulated primary human hepatocytes in 1993 (Geller *et al.*, 1993a). The sequence of the human hepatocyte iNOS clone reveals a 4145-base pair (bp) cDNA, containing a 3459-bp open reading frame that encodes a polypeptide of 1153 amino acids with a calculated molecular mass of 131 kDa. Compared to human endothelial cNOS and human neuronal cNOS, human hepatocyte iNOS displays 51 and 53% amino acid sequence identity, respectively. Overall, human iNOS displays 80% sequence homology to murine macrophage iNOS. Similar to other NOS isoforms, hepatocyte iNOS contains consensus recognition sites for the cofactors flavin mononucleotide (FMN), flavin adenine dinucleotide (FAD), and NADPH in the carboxyl half of the protein that have been shown to be important for iNOS enzyme activity. In addition, binding sites for heme, bipterin, and calmodulin are also present. The functional role of the human iNOS cDNA was confirmed by transfection of an iNOS cDNA expression vector into human kidney cells, which resulted in a substantial increase in NOS activity as detected by conversion of radiolabeled arginine to citrulline (Geller *et al.*, 1993a). Since the initial report, human iNOS cDNAs have been cloned from chondrocytes (Charles *et al.*, 1993; Maier *et al.*, 1994), the DLD-1 colon carcinoma cell line (P. A. Sherman *et al.*, 1993), the A-172 glioblastoma cell line (Hokari *et al.*, 1994), and human cardiac myocytes (Luss *et al.*, 1995). Each of these cDNAs are identical to the human hepatocyte iNOS cDNA with >99% sequence homology. Table II lists primary human cells, cell lines, or tissues that have been reliably documented to express human iNOS.

The human iNOS gene was cloned by Mudgett from a fibroblast genomic library (Chartrain *et al.*, 1994). All of the isolated clones were found to be part of a single genomic locus. The full-length human iNOS gene is 37 kb in length and is composed of 26 exons and 25 introns (Table I). This genomic structure is similar to that of human endothelial and neuronal NOS genes, and it suggests the divergence from a common ancestor. Primer extension analysis of LPS and cytokine-stimulated human hepatocyte RNA identified the transcriptional initiation site 30 bp downstream of the TATA box. Utilizing a somatic cell hybrid mapping panel and fluorescent *in situ* hybridization, the human iNOS gene was mapped to chromosome 17 at position 17 cen-q11.2 (Chartrain *et al.*, 1994). Human eNOS (Marsden *et al.*, 1993) and nNOS (Kishimoto *et al.*, 1992) reside on chromosome 7 and 12, respectively, confirming that the three NOS genes are distinct.

Protective and Pathophysiological Roles of iNOS Expression

The importance of iNOS expression in human physiological and pathophysiological conditions is increasingly clear and is the focus of a review by Kroncke *et al.*, (1998) and chapters in this book. We briefly mention that iNOS expression can result in both beneficial and detrimental actions to

Table II Human Cells and Tissues That Express iNOS

Primary cells	Cancers	Cell lines
Astrocytes	Breast	A-172 glioblastoma
Chondrocytes	Colon	AKN-1 liver epithelium
Cardiac myocytes	Melanoma	A549 lung epithelium
Eosinophils	Squamous cell	B cell lymphoma
Endometrium	Uterine	CaCO-2 adenocarcinoma

illustrate the importance of delineating the molecular mechanisms that govern iNOS expression. The large quantity of NO produced by iNOS has important antimicrobial functions (MacMicking *et al.*, 1997), and NO can inhibit the growth of viruses (Croen, 1993; Karupiah *et al.*, 1993; Saura *et al.*, 1999) and bacteria (Shiloh *et al.*, 1999). NO has been shown to have a protective effect in malaria (Anstey *et al.*, 1996; Nussler *et al.*, 1991), and polymorphisms have been identified in the human iNOS promoter that correlate with malaria “disease susceptibility” in certain populations (Burgner *et al.*, 1998; Kun *et al.*, 1998). In the immune system, NO reduces both neutrophil and platelet adhesion (Hickey and Kubes, 1997), and it has an immunoregulatory role in lymphocyte activation and allograft rejection (Bonham *et al.*, 1997; Hoffman *et al.*, 1990). In experimental endotoxemia, iNOS is widely expressed in many tissues (Salter *et al.*, 1991). The induced NO synthesis that occurs in vascular beds during sepsis is protective in solid organs such as the liver, kidney, and intestine (Harbrecht *et al.*, 1992; MacKendrick *et al.*, 1993; Markewitz *et al.*, 1993). NO is a potent vasodilator and anticoagulant that minimizes organ ischemia. Another major mechanism of iNOS protection is elicited by the antiapoptotic effects of NO (Li *et al.*, 1999). In an animal model of acute liver failure, a NO donor decreased liver damage and blocked apoptosis, whereas NOS inhibitors increased apoptosis in LPS-challenged animals (Ou *et al.*, 1997; Saavedra *et al.*, 1997). iNOS expression is also important in the normal process of wound healing (Heck *et al.*, 1992; Schaffer *et al.*, 1997; Yamasaki *et al.*, 1998).

Although NO appears to have many beneficial roles in the acute aspects of the septic response, overexpression of iNOS can be detrimental. Induced NO synthesis in blood vessel walls results in massive vasodilation and hypotension due to iNOS expression in smooth muscle cells (Busse and Mulsch, 1990; Nakayama *et al.*, 1992) and endothelial cells (Suschek *et al.*, 1993). Animal studies have shown that iNOS contributes to the vascular collapse in septic shock (Szabo and Thiemermann, 1994). Many animal models have shown that chronic, localized expression of iNOS has deleterious effects. In autoimmune diseases such as juvenile diabetes (Corbett and McDaniel, 1992; Eizirik *et al.*, 1994), arthritis (McCartney-Francis *et al.*, 1993), and immune-mediated nephritis (Weinberg *et al.*, 1994), NO is cytotoxic. Coincident expression of iNOS in neurodegenerative disease implicates NO in the pathogenesis of multiple sclerosis and other demyelinating central nervous system (CNS) lesions (Koprowski *et al.*, 1993). Furthermore, NO has been shown to cause DNA damage and is mutagenic (Wink *et al.*, 1991), and iNOS expression has been documented in several cancers (Ambs *et al.*, 1998a). Demonstrably, NO can have both beneficial and detrimental actions. Understanding the complex aspects of iNOS regulation has the potential of providing important insights and possible therapeutic strategies for a number of acute and chronic inflammatory diseases.

Characterization of iNOS mRNA Expression

There are both similarities and differences in the regulation of the human and murine iNOS genes. In general, rodent cells are more sensitive to various biological and pharmacological agents, and single agents will readily induce high-level iNOS expression. Figure 2 is a Northern blot for iNOS mRNA expression in cultured rat hepatocytes. IL-1 β is the most potent single cytokine to stimulate rat hepatocyte iNOS

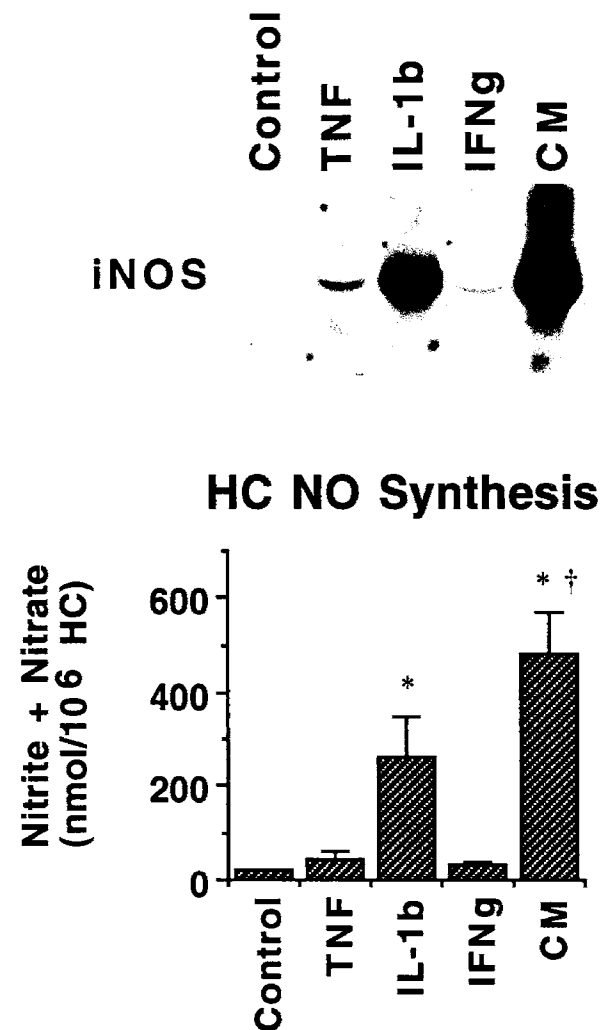

Figure 2 Effects of single cytokines and a cytokine mixture on the expression of rat hepatocyte iNOS mRNA and nitric oxide synthesis. The experiment pictured in this figure measured the expression of iNOS mRNA and the resulting nitrogen oxides that are generated in the culture medium as measured by Northern blotting and by the Greiss assay, respectively. The experiment measured the cellular iNOS mRNA and culture media nitrite + nitrate in response to media \pm 500 U/ml of TNF α , IL-1 β , or IFN γ as single agents, or together in a cytokine mixture (CM). Notice that IL-1 β alone is sufficient for the induction of hepatocyte iNOS mRNA, whereas the CM is able to induce iNOS mRNA expression in a synergistic fashion. Also note that the level of NO produced, as measured by the Greiss assay, is a reflection of the expression of iNOS mRNA. * indicates $p < 0.05$ versus control; † indicates $p < 0.05$ versus IL-1 β . Adapted with permission from Geller *et al.* (1995). *The Journal of Immunology* 155, 4890–4898. Copyright 1995. The American Association of Immunologists.

mRNA expression and NO synthesis. $\text{TNF}\alpha$ or $\text{IFN}\gamma$ alone weakly induce iNOS mRNA expression and have additive or synergistic effects when added together with IL-1 β . LPS- or cytokine-induced NO synthesis was not easily identified in human macrophages, and a debate over whether humans even possessed an inducible NOS ensued. However, an LPS- and cytokine-inducible NOS activity was eventually identified in human hepatocytes (Geller *et al.*, 1993a; Nussler *et al.*, 1992), which led to the initial cloning of the human iNOS cDNA from human hepatocytes. Characterization of human iNOS expression showed fundamental differences between mouse and humans in the regulation of iNOS transcription by cytokines. For instance, isolation of the human iNOS cDNA in hepatocytes involved a cytokine mixture (CM) that included LPS, $\text{TNF}\alpha$, IL-1 β , and $\text{IFN}\gamma$ to elicit maximal human iNOS mRNA expression. Subsequently, it was shown that various pairwise combinations of $\text{TNF}\alpha$, IL-1 β , and $\text{IFN}\gamma$ functioned additively or synergistically for induction of human hepatocyte iNOS mRNA (de Vera *et al.*, 1996a; Geller *et al.*, 1993a). Pictured in Fig. 3A is a Northern blot analyzing human iNOS mRNA expression in the AKN-1 human liver cell line in response to various cytokine combinations. As depicted, iNOS mRNA expression is undetectable in resting cells. However, in response to a cytokine mixture of $\text{TNF}\alpha$, IL-1 β , and $\text{IFN}\gamma$, a robust iNOS mRNA expression is induced. A single mRNA band at ~4.5 kb first appeared 2 hours after stimulation, peaked at 4–6 hours, and was diminished by 24 hours. Similarly, NO_2^- and NO_3^- levels were measured from the culture supernatants and were found to increase 20- to 30-fold at 24 hours after stimulation. Whereas most human cell types require a combination of cytokines to activate iNOS expression, IL-1 β alone at high doses can induce iNOS mRNA in cultures of primary human hepatocytes (Geller *et al.*, 1995) and chondrocytes (Charles *et al.*, 1993). As shown in Fig. 3B, $\text{IFN}\gamma$ alone can induce only a low level of iNOS mRNA expression. However, either $\text{TNF}\alpha$ or IL-1 β can synergize with $\text{IFN}\gamma$ for increased iNOS expression, whereas CM is the strongest inducing combination. The molecular basis for the synergistic induction of iNOS gene expression by cytokines led to investigations into iNOS transcription and iNOS promoter activities.

Deletional Analysis of the Murine and Human iNOS Promoters

Since the cloning of the mouse and human iNOS cDNAs, it is evident that the predominant mode of regulation for iNOS expression is at the level of mRNA transcription initiation (de Vera *et al.*, 1996a; Lorsbach *et al.*, 1993; Xie *et al.*, 1993). Nuclear run-on assays have shown a three- to fivefold increase in iNOS transcription rate in murine or human cells after LPS and cytokine stimulation (de Vera *et al.*, 1996a; Lowenstein *et al.*, 1993; Xie *et al.*, 1993). Interestingly, a basal nuclear transcript was seen in the unstimulated human

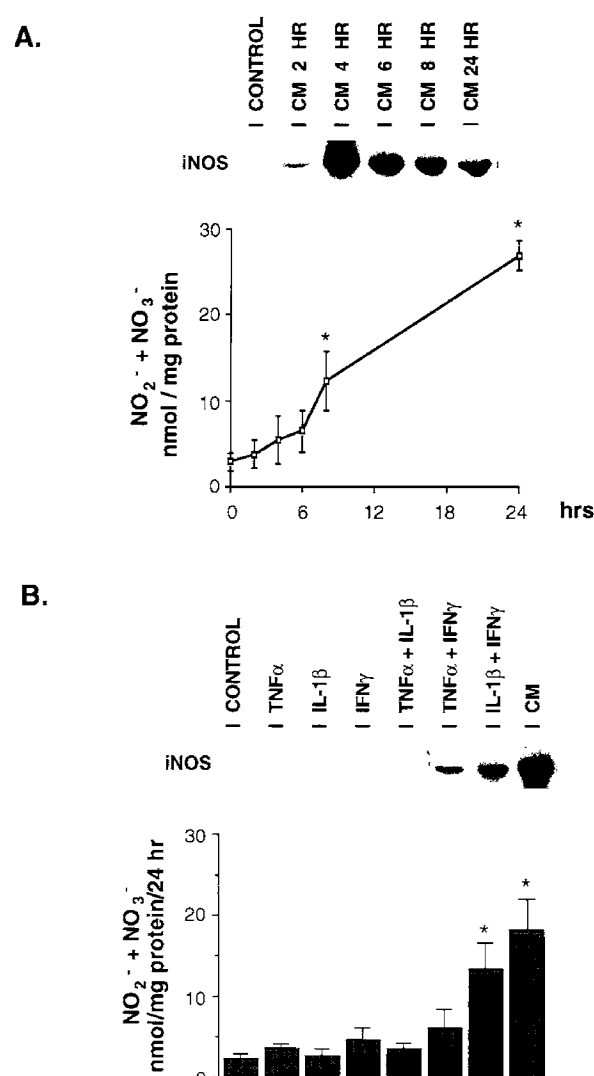

Figure 3 Multiple cytokines functioning in synergy are typically required for expression of human iNOS mRNA and subsequent NO synthesis. (A) A Northern blotting experiment for iNOS mRNA expression in AKN-1 cells was performed with RNA isolated at various time points in response to a cytokine mixture containing 1000 U/ml of $\text{TNF}\alpha$, 100 U/ml of IL-1 β , and 250 U/ml of $\text{IFN}\gamma$. Note that the peak of iNOS mRNA induction occurs around 4 hours after cytokine stimulation, and that the peak production of NO lags behind that of iNOS mRNA synthesis and continues to increase at 24 hours. (B) Multiple cytokines were tested singly, and in combination, for the ability to induce iNOS mRNA expression by Northern blotting, and for NO synthesis by the Greiss reaction. Single cytokines such as $\text{TNF}\alpha$, IL-1 β , or $\text{IFN}\gamma$ are not effective for induction of iNOS mRNA by themselves. However, cytokine synergy for the induction of iNOS mRNA is observed when either $\text{TNF}\alpha$ or IL-1 β is combined with $\text{IFN}\gamma$. Note that CM is the strongest inducing combination for both the synthesis of iNOS mRNA and for NO production. Adapted with permission from de Vera *et al.* (1996a).

cells and indicates constitutive, low-level human iNOS transcription (de Vera *et al.*, 1996a). This was unexpected, given that a basal iNOS mRNA expression is not observed in Northern blot experiments using resting primary human cells or most cell lines (see Fig. 3). This suggests that the iNOS mRNA transcript is highly labile and is rapidly degraded in

the absence of cytokine stimulation, indicating the probability of posttranscriptional regulatory mechanisms in addition to transcriptional regulation.

To illustrate the differences between the molecular regulation of the rodent and human iNOS genes, a summary of the murine and human iNOS promoters will be reviewed. In work by Xie (Xie *et al.*, 1993) and Lowenstein (Lowenstein *et al.*, 1993), a 1.7-kb segment of the 5'-flanking region of the murine iNOS gene was found to contain LPS and cytokine-responsive promoter elements. Following transfection of deletional iNOS promoter-reporter gene constructs into the macrophage cell line RAW 264.7, two discrete upstream regions (region I and II) were found to mediate inducibility by LPS and IFN γ .

These results contrast markedly with the transcriptional regulation of the human iNOS promoter where our group reported that far upstream elements in the 5'-flanking region of the human iNOS gene were required to confer cytokine-inducibility (de Vera *et al.*, 1996a). To delineate the cytokine-responsive regions of the human iNOS promoter, we isolated ~16 kb of the human iNOS gene 5'-flanking region

and generated deletional iNOS promoter constructs ranging in size from 1.3 to 16 kb. These deletional segments were then ligated in front of the luciferase reporter gene. After liposomal transfection of the iNOS promoter-luciferase reporter constructs into human liver (AKN-1) or lung (A549) epithelial cells, analysis of the first 4.7 kb upstream-demonstrated basal promoter expression, but failed to show any cytokine-inducible activity (see Fig. 4A). However, a three- to fourfold increase in promoter activity was observed in constructs extending up to -5.8 and -7.2 kb, and a ninefold increase in promoter activity was induced by cytokines after transfection of the -16-kb construct. Therefore, the functional cytokine-responsive promoter elements are located upstream from -4.7 kb in the human iNOS promoter. The three- to ninefold increase in cytokine-stimulated promoter activity with the larger constructs correlated reasonably well with the ~fivefold induction of transcription that we detected by nuclear run-on assay. To further establish that the proximal 5'-flanking region was not a critical component of the human iNOS promoter, we deleted 2.6 kb of DNA from the 5'-flanking region (-2.1 to -4.7 kb) in the context of

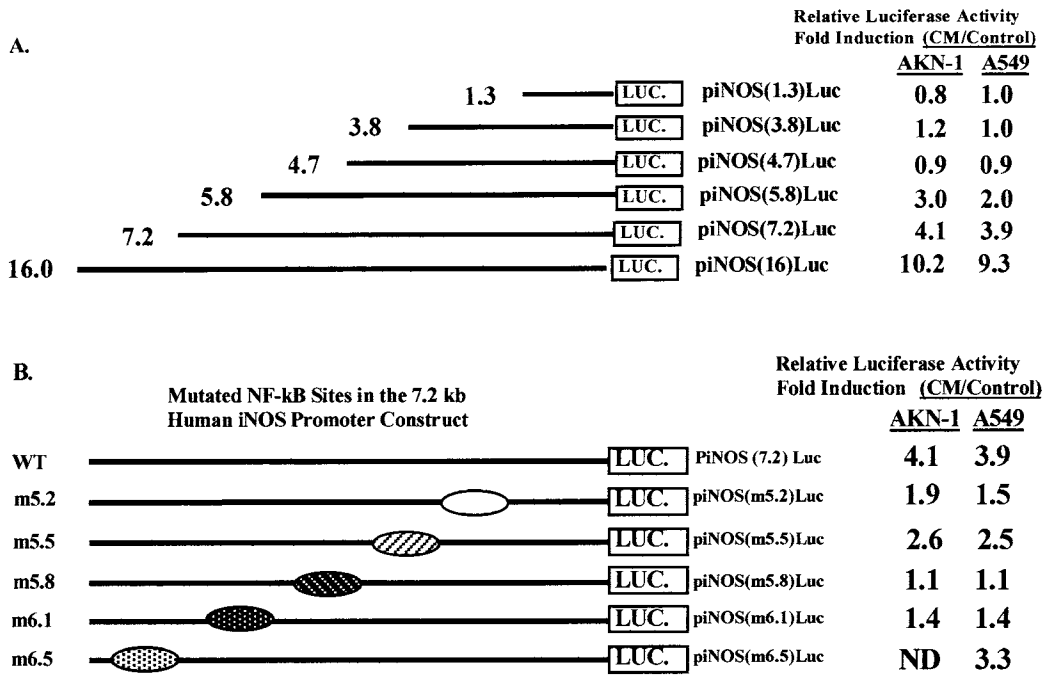

Figure 4 A 5' deletion and mutation analysis of iNOS promoter-luciferase reporter gene constructs localizes cytokine-responsive NF- κ B binding sequences far upstream in the human iNOS promoter. (A) Various lengths of iNOS promoter DNA (-1.3, -3.8, -4.7, -5.8, -7.2, and -16 kb) were fused to a luciferase reporter vector, transfected into either AKN-1 or A549 cells, and either unstimulated or stimulated with a cytokine mixture (CM) containing 1000 U/ml TNF α , 100 U/ml IL-1 β , and 250 U/ml IFN γ . Values are expressed as -fold induction of light units from CM-stimulated cells divided by the light units from unstimulated cells. The relative light units were normalized to the expression of β -galactosidase units expressed from a cotransfected, internal control β -gal expression plasmid. Notice that the cytokine-inducibility of the luciferase reporter plasmids requires iNOS promoter DNA sequence upstream of -4.7 kb. (B) DNA sequence analysis and site-directed mutagenesis of iNOS promoter-reporter plasmids identify multiple, cytokine-responsive NF- κ B sequence elements. Site-directed mutagenesis of the -7.2 kb iNOS promoter-reporter plasmids was utilized to assess the function of five putative NF- κ B promoter elements localized between -5.2 and -6.5 kb of 5'-flanking iNOS promoter DNA. Normalized values are expressed as relative light units from CM-stimulated cells divided by the relative light units from unstimulated cells. Notice that mutation of the different NF- κ B elements eliminates the cytokine inducibility of the iNOS promoter-reporter plasmids to varying extents. Adapted with permission from Taylor *et al.* (1998).

the 7.2 kb iNOS–luciferase promoter construct. Transfection and cytokine stimulation in either human cell line maintained the same ~fourfold induction as the full-length 7.2-kb iNOS–luciferase promoter construct, confirming that this proximal region was dispensable (de Vera *et al.*, 1996a; Taylor *et al.*, 1998).

Studies by other groups have verified that the upstream regions are required for cytokine-inducible human iNOS promoter activity. Similar to our results in human liver and lung cells, Laubach and Marks were unable to demonstrate any inducible activity with a 3.7-kb iNOS promoter construct in human DLD-1 colon cells (Laubach *et al.*, 1997) and human A549 cells (Marks-Konczalik *et al.*, 1998). Kolyada has also demonstrated no LPS and IFN γ inducibility in human vascular smooth muscle cells transfected with a 1.1-kb human iNOS promoter segment (Kolyada *et al.*, 1996). Work by Linn identified an enhancer region from –8.7 to –10.7 kb in the human iNOS promoter that confers IL-1 β and IFN γ responsiveness in DLD-1 cells (Linn *et al.*, 1997). Since the initial isolation of the murine and human iNOS promoters, much work has been done to define the *cis*- and *trans*-activating factors important for regulating iNOS transcription. A summary of these findings will be reviewed.

The Critical Importance of the NF- κ B Signaling Pathway

The mechanisms by which the NF- κ B family of DNA binding proteins function to regulate gene transcription has been the subject of intense scientific scrutiny for more than a decade. The NF- κ B family of DNA binding proteins are typically resident in the cytoplasm in various homo- and heterodimeric associations and are retained in the cytoplasm by the inhibitory κ B (I κ B) family of proteins until an appropriate signal is transduced. A large set of environmental and biological signals can initiate the NF- κ B signal transduction cascade. Signal transduction results in the phosphorylation and subsequent ubiquitination of the I κ B family of proteins, which targets the I κ B protein for proteolytic degradation by the “proteasome.” As a result of I κ B degradation, the dimeric NF- κ B proteins are now free to enter the nucleus, bind to specific DNA sequences, and regulate gene transcription by interactions with basal transcription factors.

Until more recently, the manner in which various agonists signal the phosphorylation and subsequent degradation of I κ B has remained a mystery. However, progress has identified the signaling pathways through which TNF α or IL-1 β -receptor interactions mediate the phosphorylation of serine-32 and serine-36 in the I κ B protein. Phosphorylation of serine-32 and serine-36 in the I κ B proteins targets the I κ B for ubiquitination and subsequent degradation by the proteasome. Following receptor engagement, TNF α receptor-associated factors (TRAF 2 or 6) interact with and activate the NF- κ B inducing kinase (NIK) complex. Then, the activated NIK complex phosphorylates and activates the inhibitory κ B kinase (IKK) complex. Activated IKK can directly

phosphorylate serine-32 and serine-36 of the I κ B protein, which is then ubiquitinated and degraded by the proteasome, thereby releasing the NF- κ B dimer to enter the nucleus. Other kinases have also been shown to phosphorylate serine-32 and serine-36 or other amino acid residues in the I κ B proteins. However, the functional importance of serine-32 and serine-36 phosphorylation in I κ B degradation and NF- κ B activation is well established. For reviews of the NF- κ B signal transduction cascade, see Baldwin (1996), Ghosh *et al.* (1998), and Mercurio and Manning (1999).

Early studies identified NF- κ B as an important transcription factor in the LPS-induced expression of iNOS in the murine RAW 264.7 macrophage cell line. Deletional analyses of iNOS promoter–reporter plasmids were utilized in mapping the LPS- and IFN γ -inducible elements to within –1.7 kb upstream of the mouse iNOS mRNA start site (Lowenstein *et al.*, 1993; Xie *et al.*, 1993). A more detailed mutational analysis revealed the presence of a functional NF- κ B DNA-binding sequence at –85 to –76 bp from the transcription start site that, when mutated, lost the ability to bind NF- κ B proteins and to activate LPS-induced reporter expression (Xie *et al.*, 1994).

Other investigators looking at LPS- or cytokine-induced iNOS transcription also discovered an important role for NF- κ B. However, important differences were being identified in the regulation of iNOS expression in different cell types. For instance, in mouse macrophages, the downstream NF- κ B site between –85 to –76 is apparently more important than the upstream NF- κ B site at –971 to –962 for LPS inducibility (Xie *et al.*, 1994). However, in IL-1 β ; TNF α ; and IFN γ -stimulated vascular smooth muscle, the upstream NF- κ B site at –971 to –962 is more functional (Spink *et al.*, 1995). Furthermore, both LPS induction and the synergistic response to LPS plus IFN γ were mapped to an upstream enhancer DNA sequence that included the upstream NF- κ B site at –971 to –962 (Alley *et al.*, 1995; Lowenstein *et al.*, 1993). Both the upstream and the downstream NF- κ B sequence elements have been shown by numerous investigators to bind various NF- κ B family members *in vitro* in different cell types and in response to differing stimuli. The compiled results of the *in vitro* NF- κ B protein–iNOS promoter DNA interactions are summarized by Murphy (1999). In general, these studies reveal that particular NF- κ B proteins bind to different NF- κ B sequences with distinct affinities in a cell type- and stimulus-dependent fashion, revealing a fine complexity in the NF- κ B regulation that is not fully understood at this time.

The apparent differences between regulation of iNOS gene transcription in different cell types and in different species has been a source of controversy, while providing an impetus to understand these differences on a mechanistic basis. Nonetheless, an important role for the NF- κ B proteins in the regulation of human iNOS transcription has been demonstrated. When we sequenced the human iNOS promoter region upstream to –7.2 kb, numerous putative NF- κ B response elements were identified. Pharmacological NF- κ B inhibitors significantly suppressed cytokine-stimulated iNOS

mRNA expression and NO synthesis, suggesting that NF- κ B is involved in the induction of the human iNOS gene. To determine whether any of the putative NF- κ B elements in the region upstream from -4.7 kb were functional, site-directed mutagenesis was used to generate five additional 7.2-kb constructs, each with a 2-bp mutation in the core sequence of the NF- κ B element (see Fig. 4B). These mutant NF- κ B promoter constructs were transfected into human cells and then stimulated with cytokines to detect inducible promoter activity. The mutation at -5.8 kb resulted in loss of both basal and inducible promoter activity, whereas mutations of the sites at -5.2, -5.5, and -6.1 kb decreased inducible promoter activity by 60, 45, and 65%, respectively (Taylor *et al.*, 1998). The NF- κ B mutant at site -6.5 kb retained the full cytokine inducibility typically seen with the 7.2-kb construct. The results showed that the NF- κ B motif at -5.8 kb is required for cytokine-induced promoter activity, whereas the sites at -5.2, -5.5, and -6.1 kb have a cooperative effect. Another NF- κ B site at -8.2 kb in the human iNOS promoter has also been shown to be functional (Marks-Konczalik *et al.*, 1998).

To demonstrate NF- κ B DNA-binding activity in human liver (AKN-1) and lung (A549) cells, gel shift assays were done using the site-specific NF- κ B oligonucleotide at -5.8 kb. Basal levels of NF- κ B DNA binding were seen in control cells (see Fig. 5). The addition of the cytokine TNF α or IL-1 β induced a strong gel shift complex for NF- κ B, whereas IFN γ had no effect. All three agents together (CM) also induced DNA-binding activity for NF- κ B, and the appearance of this complex was markedly suppressed by the addition of the antioxidant pyrrolidine dithiocarbamate (PDTc), further implicating NF- κ B in iNOS expression. Specificity for NF- κ B was demonstrated by competition assay with a 100-fold excess of unlabeled NF- κ B oligonucleotide. Competition assays with excess unlabeled mutant oligonucleotide failed to compete for the NF- κ B-DNA complex, demonstrating specificity for NF- κ B. Antibody supershift studies in the A549 lung cells showed the presence of both p50 and p65 subunits of NF- κ B in the complex. Additional studies indicate that the proximal promoter NF- κ B sequence located at -106 to -115 bp in the human iNOS promoter DNA is not sufficient to confer cytokine inducibility to iNOS transcription (de Vera *et al.*, 1996a; X. Zhang *et al.*, 1996). However, this NF- κ B sequence appears to be important for basal expression of iNOS and can functionally cooperate with other NF- κ B sequences for cytokine inducibility (Marks-Konczalik *et al.*, 1998; Nunokawa *et al.*, 1994).

It should be noted that a variety of agents besides LPS, TNF α , or IL-1 β can induce the nuclear translocation and activation of NF- κ B. Importantly, many of these inducers of NF- κ B are also inducers of iNOS expression in some cell types (see Table III). For instance, the β -amyloid protein observed in Alzheimer's disease is an efficient inducer of both NF- κ B activation and iNOS expression in mouse astroglial cells (Akama *et al.*, 1998; Bonaiuto *et al.*, 1997). Furthermore, gp120 of human immunodeficiency virus (HIV) induces NF- κ B in immune cells (Briant *et al.*,

1998a,b; Shatrov *et al.*, 1996), and both gp41 and gp120 activate iNOS expression (Adamson *et al.*, 1996; Kong *et al.*, 1996). Other agents that induce NF- κ B activation and subsequent iNOS expression include FcE receptor signaling by antigen-IgE immune complexes (Bayon *et al.*, 1997; Bidri *et al.*, 1997), insulin-like growth factor-II (IGF-II) (Kaliman *et al.*, 1999), double-stranded RNA (dsRNA) (Heitmeier *et al.*, 1998), reactive oxygen species (ROS) (Adcock *et al.*, 1994; Hoffmann *et al.*, 1996), lipid secondary messengers (Katsuyama *et al.*, 1998; Pahan *et al.*, 1998; Welsh, 1996), cAMP analogs (Kleinert *et al.*, 1996a,b; Pahan *et al.*, 1997), IL-12 (Grohmann *et al.*, 1998; Salvucci *et al.*, 1998), phorbol esters (Diaz-Guerra *et al.*, 1996a), low environmental pH (Bellocq *et al.*, 1998), hyaluronic acid derivatives (McKee *et al.*, 1997), and parasite-derived peptides (Velasco *et al.*, 1997).

In vivo footprinting technology has also suggested an important role for the NF- κ B proteins in iNOS expression in living mouse cells. In particular, the downstream NF- κ B sequence is occupied by proteins under basal conditions and in LPS-stimulated cells, whereas the upstream sequence is only occupied in response to LPS (Goldring *et al.*, 1996, 1998). Importantly, p65-NF- κ B deficient mice die *in utero* of massive hepatic apoptosis, whereas the p50 and c-Rel null mice survive to term but are immunologically compromised. It is significant that activated macrophages from c-Rel knockout mice are partially defective for iNOS expression (Grigoriadis *et al.*, 1996). In addition, data utilizing adenovirus gene transfer expressing either a dominant negative I κ B α protein (Jobin *et al.*, 1998) or a dominant negative RelA (p65) NF- κ B protein (Soares *et al.*, 1998) support a critical role for NF- κ B in cytokine-induced iNOS expression in endothelial cells. Our data indicate the same is true in primary rat hepatocytes. In particular, expression of the dominant negative I κ B α protein in rat hepatocytes prevented cytokine-induced NF- κ B activation and subsequent iNOS expression (Taylor *et al.*, 1999). Furthermore, TNF α is a well-studied cytokine that signals through the NF- κ B pathway, and TNF α receptor knockout mice are defective in the induction of iNOS by cytokines (Da Silva *et al.*, 1997; Salkowski *et al.*, 1996; Vieira *et al.*, 1996). In summary, a tremendous variety of data indicate a critical role for NF- κ B proteins in the regulation of rodent and human iNOS transcription in a variety of cell types in response to various signals. Although NF- κ B is a critical transcription factor mediating iNOS expression, it is clear that other signaling pathways are also involved.

The Importance of the Interferon-Jak-Stat Pathway for iNOS Induction

γ -Interferon is a well-characterized inducer of iNOS transcription in many different cell systems, particularly murine macrophage cell lines. Signal transduction by the type I interferons (IFN α/β) and type II interferon (IFN γ) has been

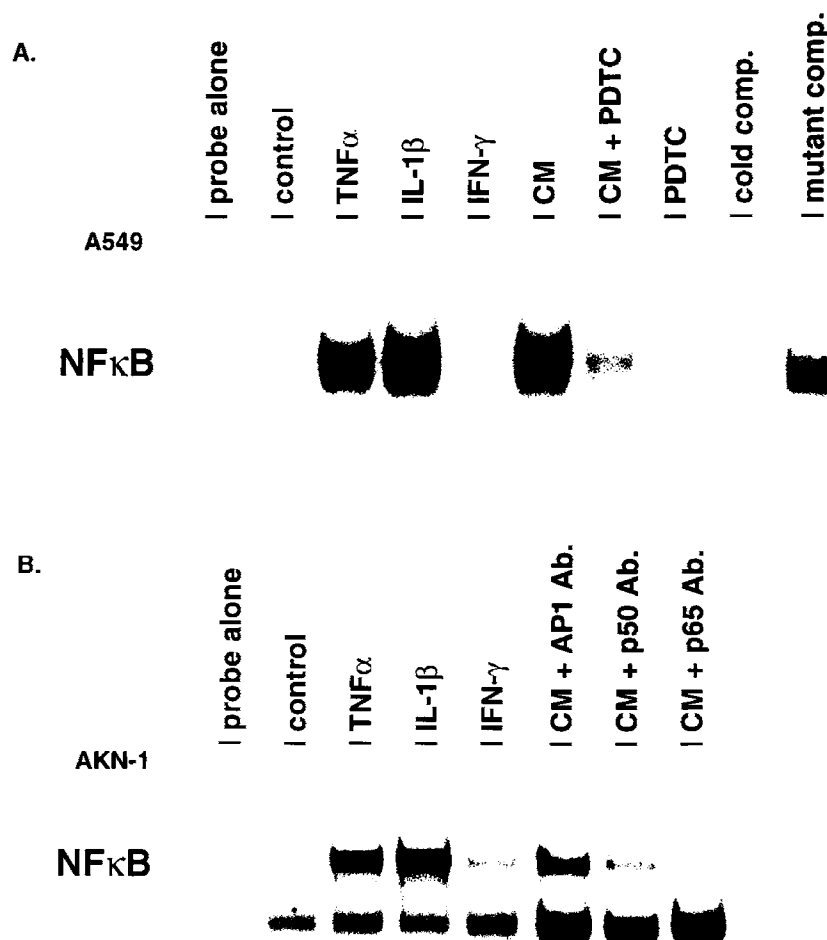

Figure 5 The functional NF- κ B-like element at -5.8 kb of the human iNOS promoter is a DNA binding sequence for cytokine-induced nuclear NF- κ B proteins. The experiments pictured are gel mobility shift assays which measure nuclear protein binding to radiolabeled DNA sequence, resulting in the formation of a protein–DNA complex. Protein–DNA complexes migrate more slowly than free DNA during native gel electrophoresis. Only the protein–DNA complexes are depicted. Notice that the lane labeled, “probe alone” does not result in a protein–DNA complex. Additionally, the nuclear DNA binding proteins that are “induced” on the addition of either TNF α , IL-1 β , or CM to A549 human lung epithelium (A) or AKN-1 human liver (B) cell cultures are inhibited by addition of the NF- κ B inhibitor PDTC. The radioactive protein–DNA complex is a specific molecular interaction, since an excess of nonradioactive DNA can compete with the radioactive probe for protein binding (cold comp). The addition of a DNA sequence mutated in the NF- κ B recognition sequence (mutant comp) fails to compete with the radiolabeled probe, indicating that the protein binding to the DNA has sequence specificity for the NF- κ B element. Additionally, notice that the addition of antibody to p50 and p65 NF- κ B will specifically eliminate the formation of the NF- κ B protein–DNA complex, whereas the addition of control AP-1 antibodies does not affect formation of the NF- κ B–DNA complex. Adapted with permission from Taylor *et al.* (1998).

shown to involve the Jak–Stat signaling pathway. Typically, the binding of interferons to specific cell surface receptors results in the activation of an intrinsic or receptor-associated tyrosine kinase (i.e., a Jak or a Tyk kinase). Subsequently, the active tyrosine kinase(s) will phosphorylate important tyrosine residues in the Stat proteins. Tyrosine-phosphorylated Stat proteins can then form homo- or heterodimers with other Stat proteins. Tyrosine phosphorylation of Stat proteins is required for dimerization, nuclear entry, and DNA binding

activities. Once in the nucleus, the active Stat dimers bind to particular sequence elements in the vicinity of target genes, interact with general transcription factors, and thereby regulate differential gene transcription. In the case of IFN γ , receptor engagement typically involves activation of Jak1 and Jak2 kinases, which then phosphorylate and activate Stat1 homodimers that enter the nucleus and bind to the IFN γ activating sequence (GAS) elements in regulated target genes. As for IFN α or IFN β , receptor engagement activates

Table III Various Agents That Induce the Nuclear Translocation and Activation of NF- κ B^a

Activating stimuli	Signaling pathways	Downstream effectors
1. LPS and CD14 LPS and Toll receptors	NIK/IKK??? NIK/IKK??? Jak ???	NF- κ B, NF- κ B Stat CREB, C/EBP, Oct/Brn3
2. TNF α	Traf 2-NIK/IKK Src-I κ B Jak	NF- κ B NF- κ B Stat 1
3. IL-1B	Traf 6-NIK/IKK	NF- κ B,
4. INF γ	Jak-Stat	Stat1
5. IFN α /B	Jak-Stat	Stat1, Stat2, IRFs
6. IL-6	???	CREB, C/EBP, Oct/Brn3
7. IGF-II	PI-3-kinase	NF- κ B
8. IL-12	???	NF- κ B
9. IgE-antigen-FCR complex	??? Jak???	NF- κ B Stats
10. dsRNA	NIK/IKK and/or PKR???	NF- κ B, Stats
11. Viral proteins (HIV gp120)	NIK/IKK	NF- κ B
12. Parasite-derived peptide	???	NF- κ B
13. Hyaluronic acid fragment	???	NF- κ B
14. β Amyloid protein	???	NF- κ B
15. cAMP agonists	PKA??? PKA	NF- κ B CREB
16. Lipid secondary messengers	PLC-PKC-MAP kinase ???	AP-1 family??? NF- κ B
17. Hypoxia and picolinic acid	??? ???	HIF-1 NF- κ B
18. ROS	Glutathione status??? jak kinase???	NF- κ B Stat

^a??? indicates that the precise signaling pathways or downstream effectors by which the activating stimuli are transduced are either speculative or unknown.

the Jak2 and/or Tyk2 kinases, which typically tyrosine phosphorylate both Stat1 and Stat2. In this case, Stat1-Stat2 heterodimers are formed that subsequently interact with the interferon regulatory factor (IRF) family of DNA binding proteins, enter the nucleus, and bind to a distinct DNA sequence element called IRSE (interferon response sequence element). Additionally, IFN α and IFN β signaling can also result in the activation of Stat1 homodimers that interact with GAS elements. For excellent reviews of the interferon-responsive Jak-Stat-IRF pathway, see Darnell (1998) and Stark *et al.* (1998).

Sequencing and mutagenesis of murine iNOS promoter-reporter constructs have identified functionally important interferon responsive elements that are required for the synergistic activation of iNOS transcription by LPS and IFN γ (Lowenstein *et al.*, 1993; Xie *et al.*, 1993). A functional ISRE element at -913 to -923 was shown to bind LPS and IFN γ -activated ISGF3, which contains Stat1, Stat2, and IRF-1 proteins in a ternary complex with DNA (Martin *et*

al., 1994). Furthermore, IRF-1 knockout mice were shown to be defective in the induction of iNOS transcription in macrophages in response to LPS and IFN γ (Fujimura *et al.*, 1997; Kamijo *et al.*, 1994; Martin *et al.*, 1994; Salkowski *et al.*, 1996). In addition, both IFN γ knockout mice (Vieira *et al.*, 1997) and IFN γ receptor knockout mice (Kamijo *et al.*, 1993) are also defective in iNOS induction. Finally, a functionally important GAS element that binds IFN γ -induced Stat1 homodimers has been identified in the murine iNOS promoter and is important for LPS plus IFN γ -induced iNOS expression in mouse macrophages (Gao *et al.*, 1997). While a requirement for Stat1 or Stat2 in IFN γ -induced iNOS expression has not been reported utilizing gene knockout technology, the importance of the IFN-Jak-Stat pathway is well established in the experiments described above.

For human iNOS expression, identification of the pathways involved in the response to IFN γ for iNOS induction is an active area of investigation. One report has suggested the involvement of the IFN γ -Jak2-Stat1 pathway (Kleinert

et al., 1998), but the iNOS promoter elements that bind either Stat1 dimers or the ISGF3 complex have not been described. However, many reports have investigated IFN γ -induced Jak kinase and Stat activation by relying on the use of tyrosine kinase inhibitors to suggest the involvement of the IFN γ -Jak2-Stat1 pathway for iNOS expression. It should be noted that the tyrosine kinase inhibitors are rather nonspecific. Indeed, herbimycin A is an effective inhibitor of Jak2 kinase, but it is also an effective inhibitor of NF- κ B DNA binding activity (Iwasaki *et al.*, 1992; Mahon and O'Neill, 1995; Nishiya *et al.*, 1995). Additionally, whereas tyrophostin B42 is reportedly a specific inhibitor of Jak2 kinase, it is also an effective blocker of NF- κ B activation (B. S. Lee *et al.*, 1997). Therefore, reliance on these inhibitors to assign strict causality to the IFN γ -Jak2-Stat1 pathway for iNOS induction should be cautioned.

Figure 6 is a gel shift assay for Stat1 α DNA-binding activity in A549 human lung cells using a consensus oligonucleotide (hSIE) for Stat1 α . IFN γ alone or as a component of CM induces Stat1 activity. We have identified a Stat1 binding sequence at approximately -5.2 kb in the human iNOS promoter that is required for induction of a luciferase reporter construct in response to CM (Taylor *et al.*, 1998). The element is predicted to be a NF- κ B binding sequence overlapping with a GAS element. Gel shift data indicate that the

-5.2 element is a very weak NF- κ B binding element, but it will bind to nuclear Stat1 protein. Similar to the mouse promoter, but located far upstream in the human promoter, functionally important NF- κ B (-5.8 kb) and Stat1 (-5.2 kb) binding elements are found in relative close proximity. Current experiments utilizing wild-type and dominant negative Stat1 expression plasmids, and also human 2fTGH fibroblasts and their Stat1 mutant derivative (U3A), indicate an important role for Stat1 in regulation of human iNOS mRNA expression.

LPS is an important inducer of iNOS expression, and the ability of LPS to activate signaling pathways and iNOS expression remains an intense area of investigation. In this regard, LPS has been identified as an inducer of NF- κ B in murine and human macrophages (Denlinger *et al.*, 1998; Goldring *et al.*, 1998). LPS is also an efficient inducer of *de novo* IFN α and IFN β synthesis in macrophages. The ability of LPS to induce iNOS in mouse macrophages requires the synthesis of and subsequent autocrine signaling by IFN β (Gao *et al.*, 1998). Therefore, LPS not only induces NF- κ B, but can also induce the IFN β -Jak-Stat pathway, resulting in the activation of the ISGF3 transcription factor complex.

The host response to viral infection involves the immunoregulatory function of IFN γ as a T helper cell type I (Th1) cytokine. Furthermore, dsRNAs produced by viruses are potent inducers of the type II interferons, IFN α/β , which are important in the antiviral response. This response involves the action of the dsRNA-activated protein kinase (PKR). It has been reported that IFN γ can activate the expression of PKR, whereas IFN α/β or dsRNA are potent inducers of PKR enzyme activity. An important function for dsRNA-activated PKR is to shut down the host protein translation machinery in virus-infected cells. This involves the dsRNA-activated auto-phosphorylation of PKR and subsequent PKR-dependent phosphorylation of the ribosomal eukaryotic translation initiation factor IIA (see Darnell, 1998 and Stark *et al.*, 1998). Interestingly, dsRNA is an important inducer of NF- κ B in astroglial cells through effecting I κ B degradation, and this results in iNOS expression in cells also exposed to IFN γ (Heitmeier *et al.*, 1998). Intriguingly, macrophages from PKR knockout mice are defective for NF- κ B activation and IRF-1 induction by dsRNA and IFN γ (Kumar *et al.*, 1997). Additionally, PKR has been shown to activate NF- κ B by inducing I κ B degradation (Kumar *et al.*, 1994). Therefore, it appears that the interferons could function through multiple pathways in regulating iNOS expression. Viral RNA can activate NF- κ B, PKR, and induce interferon expression. IFN γ induces Jak-Stat1 pathway activation and PKR expression. The type II interferons IFN α/β are effective in ISGF3 activation and could signal a PKR-dependent NF- κ B activation. These findings signify a very complex immune response that would involve the interferons in Th1 type immunoregulation, interferon-induced iNOS, and NO-induced antimicrobial activities and that would involve the interrelated actions of the PKR, the Jak-Stat, and the NF- κ B signal transduction pathways.

Figure 6 γ -Interferon induces nuclear, Stat1 DNA-binding activity. The gel shift assay depicted utilizes nuclear proteins isolated from human A549 lung epithelium stimulated for 2 hours with TNF α , IL-1 β , IFN γ , or CM as indicated. The experiment utilized a radiolabeled consensus SIE DNA sequence, which is a high affinity binding site for Stat1 α homodimers. In A549 cells, only IFN γ or CM induces nuclear, Stat1 DNA-binding activity. The identification of these protein-DNA interactions as Stat1 protein-DNA interactions has been verified by use of competition assays and by antibody supershift assays.

Cytokine Synergy for Induction of iNOS mRNA Involves NF- κ B and Interferon–Jak–Stat–IRF Pathways

Although IFN γ alone can efficiently induce iNOS expression in some murine cell types, it is generally not effective alone for iNOS mRNA induction in human cell types. However, IFN γ has been shown to cooperate for iNOS expression with LPS (Deng *et al.*, 1993; Geller *et al.*, 1993b; Lorsbach *et al.*, 1993; Lowenstein *et al.*, 1993; Stuehr and Marletta, 1987; Xie *et al.*, 1993), TNF α (Cox *et al.*, 1992), IL-1 β (Geller *et al.*, 1993b, 1995), IL-2 (Cox *et al.*, 1992; Deng *et al.*, 1993), dsRNA (Heitmeier *et al.*, 1998), β -amyloid protein (Bonaiuto *et al.*, 1997), phorbol esters (Jun *et al.*, 1994; Yoon *et al.*, 1994), and agents that elevate or mimic intracellular calcium (Raddassi *et al.*, 1994) or cAMP (Kleinert *et al.*, 1996a,b; Koide *et al.*, 1993; Kunz *et al.*, 1994).

Intriguingly, many different rodent cell types have been shown to express iNOS in response to single biological agents, including LPS, TNF α , IL-1 β , or IFN γ . However, in mouse macrophages, LPS-induced iNOS expression requires the *de novo* synthesis of and autocrine actions of IFN β , since antibodies to IFN β can specifically attenuate the LPS-induced iNOS expression (Fujihara *et al.*, 1994a; Gao *et al.*, 1998). Additionally, IL-1 β alone is sufficient to induce iNOS expression in rat hepatocytes (Geller *et al.*, 1995). However, the IL-1 β -induced iNOS expression in rat hepatocytes requires the autocrine synthesis and function of IFN γ , since antibodies or antisense RNA strategies directed against IFN γ will block the IL-1 β -induced iNOS expression (Schroeder *et al.*, 1998). IFN γ alone has been shown to induce at least some iNOS expression in many different rodent cell types including hepatocytes and vascular smooth muscle (VSM), and in a few human cell types such as hepatocytes and the AKN-1 and DLD-1 cell lines. However, it is interesting that there is at least some level of “constitutive” nuclear NF- κ B protein in VSM (Lawrence *et al.*, 1994; Shin *et al.*, 1996), hepatocytes (R. W. Ganster and D. A. Geller, personal observation), AKN-1 cells (Taylor *et al.*, 1998), and DLD-1 cells (Kleinert *et al.*, 1998). Furthermore, IFN γ is a weak inducer of NF- κ B in rat hepatocytes (Duval *et al.*, 1996) and a strong inducer of NF- κ B in the mouse renal epithelium cell line MCT (Amoah-Apraku *et al.*, 1995). Finally, TNF α alone is an effective inducer of NF- κ B activation and iNOS expression in mouse macrophages, and it is interesting that TNF α can efficiently activate NF- κ B and is also an activator of the Jak2–Stat1 pathway (Guo *et al.*, 1998). In summary, iNOS expression is typically regulated in a synergistic manner by a combination of inducers of the NF- κ B pathway and by the interferon–Jak–Stat pathway. In the instances where single agents are effective for iNOS induction, both the NF- κ B and Jak–Stat pathways are activated by the stimuli, or one pathway is constitutively activated. Several mechanisms describing the synergistic effects of NF- κ B inducers with Jak–Stat pathway inducers in

regulating gene expression have been suggested (Drew *et al.*, 1995; Lowenstein *et al.*, 1993; Neish *et al.*, 1995; Ohmori *et al.*, 1997; Pine, 1997; Shen and Stavnezer, 1998; Taylor *et al.*, 1998). However, the molecular basis of this cytokine-induced transcriptional synergy is an important and unresolved question and likely involves substantial integrations of the NF- κ B and Jak–Stat pathways.

The Complex Effects of the cAMP-Dependent Protein Kinase A Pathway on iNOS Transcription

Although the cAMP response pathway has been investigated for decades, many questions remain about the manner by which cAMP regulates mRNA transcription (for review, see Montminy, 1997). Likewise, the effects of cAMP and agonists that increase the intracellular concentration of cAMP on iNOS transcription are complex and the molecular mechanisms remain obscure. For instance, in rat mesangial (Eberhardt *et al.*, 1998; Kunz *et al.*, 1994) or VSM cells (Imai *et al.*, 1994; Koide *et al.*, 1993), agents that mimic or elevate intracellular cAMP concentrations such as cholera toxin, forskolin, isoproterenol, or cAMP analogs all activate the transcription of iNOS. Furthermore, agents that activate the cAMP pathway can cooperate with TNF α , IL-1 β , IFN γ , or activators of protein kinase C in an additive or synergistic fashion for the induction of iNOS transcription in a variety of cell types (Imai *et al.*, 1994; Koide *et al.*, 1993; Kunz *et al.*, 1994; Mullet *et al.*, 1997; Scott-Burden *et al.*, 1994). In contrast, agonists that activate the cAMP–protein kinase A (PKA) pathway in brain astroglial cells do not induce iNOS expression and are inhibitory to the LPS- or cytokine-induced iNOS transcription (Pahan *et al.*, 1997). In liver Kupffer cells and hepatocytes, prostaglandins or cAMP–PKA activators inhibit the LPS- or cytokine-induced iNOS expression (Harbrecht *et al.*, 1997; Mustafa and Olson, 1998). In macrophage cell lines and primary astroglia, the effects of cAMP–PKA agonists and mimics are predominantly inhibitory for iNOS expression (Harbrecht *et al.*, 1997; Morris *et al.*, 1998; Mullet *et al.*, 1997; Mustafa and Olson, 1998; Pahan *et al.*, 1997). However, in peritoneal macrophages, iNOS transcription is reported to be activated by cAMP or PKA activators (Pahan *et al.*, 1997). In primary murine splenic macrophages, cAMP or prostaglandin E₂ can synergize with TNF α plus IFN γ to activate iNOS expression, whereas these same agents are inhibitory for LPS-induced iNOS (Schwacha *et al.*, 1998). The conflicting actions of cAMP on iNOS expression probably reflect differential effects of cAMP on cell metabolism as well as differences in cell type or culture conditions. Furthermore, the complex effects of cAMP on iNOS transcription in different cells types may relate both to direct effects of the cAMP–PKA pathway on iNOS transcription and to indirect effects of the cAMP–PKA pathway on iNOS expression via cross talk with both the NF- κ B and the Jak–Stat pathway.

Direct regulation of iNOS expression by the cAMP–PKA pathway has been described in mesangial cells. Either IL-1 β

or cAMP can activate and cooperate for iNOS transcription in these cells, which is associated with the induction of DNA binding by the NF- κ B, CREB, and CCAAT/enhancer binding protein (C/EBP) family of DNA-binding proteins. Furthermore, a functionally responsive C/EBP element between -277 and -111 bp upstream of the rat transcription start site has been described that is capable of interacting with CREB and C/EBP family members (Eberhardt *et al.*, 1998). Importantly, cAMP is a strong inducer of CREB and C/EBP, whereas IL-1 β is a strong activator of NF- κ B. Interestingly, IL-1 β is a weak activator of induced CREB and C/EBP DNA-binding activities and is also a positive effector in upregulation of C/EBP expression (Eberhardt *et al.*, 1998). Another possible mechanism for the positive effect of cAMP on iNOS expression includes the following: protein kinase A phosphorylates *in vitro* a carboxyl-terminal serine residue in the transcription activation domain of the p65 subunit of NF- κ B, which is required for interaction with the general coactivator CBP/p300 and for transcription activation (Gerritsen *et al.*, 1997; Zhong *et al.*, 1998). Additionally, the cytoplasmic PKAc subunit is identified in a ternary association with the cytoplasmic NF- κ B-I κ B complex, and the phosphorylation of p65 by PKAc is independent of cAMP (Zhong *et al.*, 1998).

Activators of cAMP signaling or cAMP mimics can inhibit LPS- or cytokine-induced iNOS transcription. The basis for these effects are not well described. However, some studies have suggested that cAMP-PKA-dependent signaling inhibits the degradation of the I κ B induced by LPS or cytokines and thereby inhibits the ability of NF- κ B to enter the nucleus and activate iNOS transcription (Mustafa and Olson, 1998; Pahan *et al.*, 1997). Furthermore, cAMP has been shown to decrease the expression and activity of Stat1 in PHA-stimulated T cells (Ivashkiv *et al.*, 1996). Additionally, cAMP has been shown to inhibit IFN γ -induced Jak1 kinase activation and subsequent Stat1 DNA binding activity, an effect which may be associated with the recruitment of SHP-2 phosphatase to the Jak1-IFN γ -receptor complexes (Sengupta *et al.*, 1996; You *et al.*, 1999).

Another possible level of complexity is the differential cell type expression of various positive and negative CREB/CREM/ICER gene family members. Additionally, CREB proteins can directly interact with various members of the AP-1 transcription factor family, interactions that result in protein complexes which bind to distinct DNA sequences (Morooka *et al.*, 1995; Zhou and Engel, 1995). An interesting speculation as to the apparent opposite effects of cAMP on iNOS expression in different cell types would propose that NF- κ B, Stat1, CREB, AP-1/ATF, and the HMG families of transcription factors are all potentially competing for limiting amounts of CBP/p300 (Bisotto *et al.*, 1996; Gerritsen *et al.*, 1997; Horvai *et al.*, 1997; Kamei *et al.*, 1996; Lee *et al.*, 1998; Parry and Mackman, 1997; Swope *et al.*, 1996; J. J. Zhang *et al.*, 1996; Zhong *et al.*, 1998). CBP/p300 encodes a general transcription coactivator complex which intrinsically possesses and also recruits histone acetylase and deacetylase enzyme complexes to reorganize chromatin

structures. If, for instance, the binding of activated CREB protein to the iNOS promoter DNA were blocked (via any sort of repressive chromatin), then the induced CREB protein would be forced to bind to other "target genes" and could potentially sequester the essential CBP/p300 proteins to other loci. Clearly, the complex cell-specific effects of cAMP on iNOS expression need to be further examined and should provide interesting information regarding signaling pathway cooperation and interference.

Additional Signaling Pathways That Regulate iNOS Expression

Molecular dissection of the requirements for regulated iNOS expression has indicated a very important and direct role for the NF- κ B signaling pathway, the interferon-Jak-Stat pathway, and also the cAMP-PKA-CREB-C/EBP pathway. However, a variety of data suggests the involvement of other important signal transduction molecules and pathways that include cell surface receptors, IL-6 and the Oct/POU/Brn transcription factor family, the hypoxia-hypoxia inducible factor (HIF)-1 pathway, phospholipase C (PLC), protein kinase C (PKC), and the Ras-mitogen activated protein (MAP) kinase cascade. Therefore, a brief summary of these data will ensue with particular emphasis on how these "auxiliary" pathways might regulate iNOS expression either directly, or through cross talk with the NF- κ B or Jak-Stat pathways.

Treatment of immature macrophages with IL-6 can induce maturation that is coincident with iNOS expression. Furthermore, LPS or IL-6 can induce nuclear C/EBP and "octamer" DNA-binding activities on the iNOS promoter as assessed *in vitro* (Sawada *et al.*, 1997) and by *in vivo* footprinting technology (Goldring *et al.*, 1996). The signaling pathways regulated by IL-6 that result in altered DNA binding activities have not been adequately described. However, the protein binding to the octamer-like iNOS promoter sequence has been identified as Brn3a (Gay *et al.*, 1998). Importantly, promoter-reporter experiments indicate that mutation of the octamer element eliminates IL-6-induced iNOS promoter-reporter activity, and furthermore, overexpression of Brn3A can potentiate expression of iNOS mRNA. These data indicate the involvement of an IL-6 responsive signaling pathway that can induce the nuclear DNA binding activities of both the NF-IL-6 (i.e., C/EBP) and Brn3a and Brn3b proteins. Importantly, NF- κ B and C/EBP have been shown to cooperate for IL-8 (Stein and Baldwin, 1993), HIV (Ruocco *et al.*, 1996), and iNOS transcription (Eberhardt *et al.*, 1998; Sakitani *et al.*, 1998). Additionally, it appears that only Brn3, and not Oct-1 or Oct-2, are capable of *trans*-activation from the iNOS promoter (Gay *et al.*, 1998), revealing a degree of specificity in the responsiveness of the iNOS promoter to particular members of the Oct/Brn/POU family of DNA-binding transcription factors.

Recent data have highlighted the role of hypoxia in the induction of iNOS expression. Hypoxia is a stimulus for the

induction of iNOS expression in rat lung *in vivo* (Xue *et al.*, 1994). Although the intracellular signaling mechanisms that regulate gene expression in response to hypoxia are only recently being dissected, a role for HIF-1 is established (Wenger and Gassmann, 1997). A hypoxia response element in the mouse iNOS promoter at position -227 to -209 is required for the response to hypoxia and to picolinic acid in the presence of IFN γ . Additionally, this element is also required for the synergistic iNOS induction by iron chelators and IFN γ (Melillo *et al.*, 1997). Similar data have not yet been demonstrated for the human system in regard to hypoxic induction of iNOS mRNA. However, the mouse hypoxic response element is not identified in the corresponding location in the human proximal promoter sequence.

Influence of the Cell Cycle Regulatory Proteins on iNOS Expression

Recent data have shown the involvement of cell cycle regulatory components on iNOS expression including the functions of certain proto-oncogenes such as PKC, Ras-Raf-MAP kinase cascade, Fos/Jun/ATF (AP-1) family, as well as the tumor suppressor p53. Frequently observed in studies analyzing the cell cycle machinery, the particular proteins involved apparently function to varying extents in different cell types. Clearly, further investigations are essential to clarify the role of these proteins on iNOS expression.

Several studies have investigated the involvement of the MAP kinases as positive effectors of LPS- or cytokine-induced iNOS expression (Chan *et al.*, 1999; Da Silva *et al.*, 1997; Nishiya *et al.*, 1997; Pahan *et al.*, 1998; Singh *et al.*, 1996). Importantly, both pharmacological and genetic evidence has implicated various MAP kinases in the induction of mouse iNOS expression. For instance, in mouse astrocytes, a drug (FHPI) that specifically inhibits the p38 MAP kinase can block iNOS induction in response to TNF α and IL-1 β (Da Silva *et al.*, 1997). In mouse macrophages, expression of dominant negative mutants of MEKK1 and MKK4, which act upstream of p46/54 JNK/SAPK, abrogated the TNF α plus IFN γ -induced iNOS expression (Chan *et al.*, 1999). In cardiac myocytes and vascular endothelium, the p42/p44 extracellular signal-related kinase (ERK)1/ERK2 kinases have been implicated in the activation of iNOS expression by either IL-1 β or IFN γ (Singh *et al.*, 1996). Separate studies in rat C6 gliomas exposed to LPS and IFN γ suggest that expression of a dominant negative Ras protein or pharmacological inhibition of the ERK kinases do not effect iNOS expression (Nishiya *et al.*, 1997). However, others suggest that cytokine- or LPS-stimulated C6 gliomas or primary astrocytes will synergistically express iNOS in the presence of ceramides. Furthermore, this expression is inhibited by PD98059 (a MEK kinase inhibitor) or by FPT II, which is a farnesyl protein transferase inhibitor, suggesting involvement of a Ras-Raf-MAP kinase pathway for iNOS expression (Pahan *et al.*, 1998). A separate study

utilizing specific inhibitors of either protein farnesylation of geranylgeranylation in IL-1 β -induced rat primary aortic smooth muscle or hepatocytes suggested that a farnesylated protein other than Ras is required for IL-1 β -induced iNOS induction, and that a geranylgeranylated protein inhibited IL-1 β -induced iNOS expression (Finder *et al.*, 1997). Likewise, PKC inhibitors and farnesyltransferase inhibitors have also implicated a PKC-Ras-Raf-ERK kinase pathway in ventricular myocytes (Singh *et al.*, 1996). The discrepancies could possibly relate to cell type and culture differences, as well as to differences in the stimuli used to elicit iNOS induction. Additionally, it is dangerous to rely solely on pharmacological inhibition experiments to assign direct causality in connecting particular MAP kinases to iNOS expression. Importantly, the MAP kinase cascades have been implicated in the activation of NF- κ B (Briant *et al.*, 1998a,b; Ho *et al.*, 1997; F. S. Lee *et al.*, 1997; Meyer *et al.*, 1996; Nakano *et al.*, 1998; Schulze-Osthoff *et al.*, 1997; Yin *et al.*, 1998). Furthermore, MEKK1 protein is directly involved in the phosphorylation-induced activation of the IKK complex and subsequent degradation of I κ B (F. S. Lee *et al.*, 1997; Nakano *et al.*, 1998; Yin *et al.*, 1998). Hence, modulation of NF- κ B activation is likely to be an important mechanism in the regulation of iNOS induction by the MAP kinase cascades.

The Fos/Jun/ATF family of nuclear transcription factors play very important roles in the regulation of gene expression, and several of these proteins are involved in cell growth and cell cycle control (Foletta *et al.*, 1998). Indeed, the Fos and Jun proteins, which make up the heterodimeric transcription factor called AP-1, were originally identified as viral oncoproteins and are intimately involved in cell cycle regulation. Furthermore, the AP-1 proteins are very important targets of the MAP kinase cascades (Whitmarsh and Davis, 1996); hence the name JNK for the p38/Jun N-terminal kinase, which is also named the stress-activated protein kinase. Recent data suggest an important role for AP-1 in regulating iNOS expression. For instance, in response to the cytokine mixture, AP-1 DNA-binding activity was decreased while iNOS mRNA expression was induced in human DLD-1 cells. Additionally, pharmacological activators of AP-1 repressed iNOS expression in response to cytokines, implicating AP-1 as a repressor of cytokine-induced iNOS expression in DLD-1 cells. Furthermore, cotransfection of both Fos and Jun expression vectors repressed the cytokine-induced expression of a 7.2-kb human iNOS promoter-reporter construct (Kleinert *et al.*, 1998). Additional support for a negative effect of AP-1 on iNOS expression in the mouse macrophage is revealed by an increase in iNOS promoter-driven reporter expression in constructs that deleted a putative AP-1 sequence (Lowenstein *et al.*, 1993). In contrast, another study implicated AP-1-like proteins as positive effectors of iNOS transcription in human A549 lung epithelium cells. CM treatment of A549 cells increased the DNA-binding activity of Jun D and Fra-2. Additionally, AP-1 binding sequences were identified at -5301 and at -5115 bp in promoter-reporter mutagenesis experiments, and the sequences were important for cytokine-induced iNOS ex-

pression (Marks-Konczalik *et al.*, 1998). The basis for the opposite effects of AP-1 for iNOS expression is not clear but might relate to the differential expression of Fos/Jun/ATF family members in DLD-1 versus A549 cells.

The phospholipase C and protein kinase C pathway has been shown to have a dual role on iNOS expression. Studies have described either a positive (Bosca and Lazo, 1994; Diaz-Guerra *et al.*, 1996a,b; Hortelano *et al.*, 1992, 1993; Jun *et al.*, 1994; Welsh, 1996) or a negative (Fujihara *et al.*, 1994b; Hortelano *et al.*, 1992; Muhl and Pfeilschifter, 1994; Nakayama *et al.*, 1994) regulatory effect on iNOS expression. The basis for the opposite effects has not been described. However, different members of the PKC family are differentially expressed in cells and have been shown to function differentially (Fujihara *et al.*, 1994b; Muhl and Pfeilschifter, 1994). Importantly, agents that function through PKC include various lipids such as sphingomyelin, ceramide, diacylglycerol, or phorbol esters which activate PLC and hence PKC, but can also influence NF- κ B activation to varying extents (Diaz-Guerra *et al.*, 1996a; Katsuyama *et al.*, 1998; Pahan *et al.*, 1998). Additionally, these same lipids and second messengers also effect the MAP kinase cascades in an ill-defined mechanism (Pahan *et al.*, 1998; Welsh, 1996; Whitmarsh and Davis, 1996). Complicating matters further is the differential expression and functions of the Fos/Jun/ATF (AP-1) family of transcription factors, which are regulated in part by PKA, PKC, and by MAP kinases. For reviews of the cAMP-PKA, PLC-PKC, MAP kinase cascades, and AP-1 family of transcription factors see Foletta *et al.* (1998), Mons *et al.* (1998), Montminy (1997), Toker (1998), Whitmarsh and Davis (1996), and Wilkinson and Nixon (1998).

Transcription Factor Interactions That Mediate iNOS Transcription

Many of the models for regulated gene transcription involve the ability of regulated transcription factors to bind to particular DNA sequences in the vicinity of the regulated target gene. Subsequently, the transcription factors recruit various general transcription factors to the promoter via protein-protein interactions. Important proteins that are recruited to promoters by regulatory transcription factors include the TATA box binding protein (TBP) and the TBP-associated factors (TAFs) in the general transcription factor complex named TFIID. TFIID is a limiting factor that facilitates the assembly of a functional transcription initiation complex containing the RNA polymerase II (for review, see Hampsey, 1998, and Hoffmann *et al.*, 1997). Another important and limiting target of regulatory DNA binding proteins is the coactivator CBP/p300, which is recruited to promoters and facilitates the organization of a permissive chromatin environment via recruitment of histone acetylase/deacetylase complexes (for review, see Hampsey, 1998, and Imhof *et al.*, 1997). Recruitment of general transcription fac-

tors and reorganization of nucleoprotein environments are important activities that transcription factors have evolved via protein-protein interactions with enzymatic machineries that are limiting and essential.

Importantly, NF- κ B has been shown to interact directly and functionally with the TBP (Kerr *et al.*, 1993; Schmitz *et al.*, 1995; Xu *et al.*, 1993). Other transcription factors that are important in the regulation of iNOS expression that interact directly with TBP include AP-1 family members (Metz *et al.*, 1994; Ransone *et al.*, 1993) and HMG proteins (Ge and Roeder, 1994; Sutrias-Grau *et al.*, 1999). Additionally, NF- κ B p65 protein can interact with TAFs, including TAFII105 (Yamit-Hezi and Dikstein, 1998). CREB proteins also functionally interact *in vitro* with general transcription factors TFIIB and TFIID, but not TBP, indicating that CREB interactions with TFIID require the TAFs (Xing *et al.*, 1995). Importantly, NF- κ B p65, Stat1, IRF proteins, CREB, AP-1 proteins, and HMG-I can directly interact with p300/CBP, which functions in the reorganization of nucleosomal DNA as a histone acetyltransferase (Bisotto *et al.*, 1996; Gerritsen *et al.*, 1997; Horvai *et al.*, 1997; Kamei *et al.*, 1996; Lee *et al.*, 1998; Parry and Mackman, 1997; Swope *et al.*, 1996; J. J. Zhang *et al.*, 1996; Zhong *et al.*, 1998). These data suggest that activation of iNOS mRNA transcription is likely to involve multiple interactions with and hence recruitment of the general transcription machinery via TBP-TAF-TATA box associations, but also involves recruitment of chromatin remodeling machines that antagonize repressive chromatin structures.

The transcription of several other genes besides iNOS are regulated synergistically by the combination of a factor (TNF α , IL-1 β , or dsRNA) and IFN γ , including ICAM-1, IP-10, and IRF-1 (Majumder *et al.*, 1998; Ohmori and Hamilton, 1995; Ohmori *et al.*, 1997), or involve the actions of several shared transcription factors, as in the regulation of IFN β expression (Wathelet *et al.*, 1998). The transcription of iNOS, ICAM-1, IP-10, and IFN β involves the coordinated activities of the NF- κ B, Stat, and IRF families of transcription factors. Therefore, it is probable that the expression of these genes is subject to similar regulatory mechanisms. Direct protein-protein interactions between transcription factors have been shown to contribute to cooperativity in the combinatorial regulation of gene transcription by multiple signaling pathways. Protein-protein transcription factor interactions that are demonstrated to be functionally important include IRF-1-Stat (Darnell, 1998; Kamijo *et al.*, 1994; Martin *et al.*, 1994; Qureshi *et al.*, 1995; Stark *et al.*, 1998), IRF-1-NF- κ B (Drew *et al.*, 1995; Neish *et al.*, 1995), IRF-1-HMG (Neish *et al.*, 1995), NF- κ B-HMG (Lehming *et al.*, 1994; Lewis *et al.*, 1994; Perrella *et al.*, 1999; Thanos and Maniatis, 1992), and AP-1-HMG (Du and Maniatis, 1994). Many of these interactions have been described as components of a multiprotein complex named the "enhanceosome." Enhanceosome functions are very important in the synergistic regulation of IFN β transcription in response to dsRNA or cytokines. It seems surprising that the Stat proteins have not been described as an integral component of

the enhanceosome, since Stat proteins have been shown to functionally and physically interact with CBP/p300, IRF-1, AP-1, and HMG-I proteins. Furthermore, Stat6 has been shown to functionally interact with NF- κ B proteins (Bennett *et al.*, 1997; Messner *et al.*, 1997), and a direct NF- κ B–Stat6 protein–protein interaction has been identified (Shen and Stavnezer, 1998). Current biochemical and genetic experiments are suggesting direct functional interactions between the TNF α –NF- κ B pathway and the IFN γ –Stat1 pathway in human A549 epithelial and in the 2fTGH fibroblast cell lines. The regulation of iNOS, ICAM-1, IP-10, and IFN β transcription has been very valuable in the generation of information regarding mechanisms of cytokine-induced, transcriptional synergism.

In summary, significant progress has been achieved in understanding the signaling pathways, transcription factors, and promoter elements that regulate iNOS transcription. However, it is clear that the regulation of iNOS expression is very complex, and further research is required to decipher the precise signal transduction pathways and molecular mechanisms that are critical for regulated iNOS expression. Fundamental differences have been identified in the regulation of iNOS expression in different cell types and in the regulation of human versus murine iNOS gene expression. Figure 7 is a summary of the major signaling pathways and nuclear transcription factors that mediate induction of murine and human iNOS gene transcription. It should be noted that there are no reports of direct investigation into the mouse iNOS promoter with regulatory DNA that extends as

far upstream as -16 kb, as is demonstrated for the human iNOS promoter. Nonetheless, one report describes an iNOS knockout mouse that deletes the “proximal promoter” region and eliminates exons 1 through 4; intriguingly, this mouse expresses a nonfunctional, truncated iNOS protein in proper developmental fashion in response to LPS administration *in vivo* (Loihl *et al.*, 1999). These data suggest that the mouse iNOS promoter may contain cytokine responsive elements that extend beyond what has currently been investigated, and it would be interesting to know whether the NF- κ B elements that have been mapped in the human promoter from -5.2 to -6.1 kb exist in the mouse. It is also clear that the murine and human systems do share common signal transduction pathways in regulating iNOS expression, and although the differences observed are significant, these differences may reflect a subtle, quantitative difference and not necessarily a fundamental regulatory and evolutionary divergence.

Downregulators of iNOS Expression

In addition to defining the factors that upregulate iNOS gene expression, there has been great interest to define those factors that downregulate iNOS expression. Glucocorticoids are known to inhibit induced NO synthesis in several cell types (Geller *et al.*, 1993b; Knowles *et al.*, 1990), and this effect appears to be tissue and species specific. For example, Kleinert and co-workers suggested that dexametha-

Figure 7 A generic summary and comparison of the major inducers, transcription factors, and promoter elements that mediate iNOS gene expression in human and murine cells. Notice that the cytokine responsive promoter elements that have been identified in the murine iNOS promoter are all located within -1 kb of 5' iNOS promoter DNA, whereas functional promoter elements in the human system have been localized between -5.1 and -8.2 kb of 5'-promoter DNA. In both systems, NF- κ B elements are critical to the regulation of iNOS transcription. Functionally important elements in the response to interferons that bind to Stat1 homodimers (GAS) or Stat1–Stat2 heterodimers in association with IRF-1 proteins (ISRE) have been identified in the mouse promoter. A role for the interferon–Jak–Stat–IRF-1 pathway in humans cells is clear, but the promoter elements that mediate this regulation have yet to be described. The hypoxia response element (HRE) identified in the murine promoter is not conserved in the human iNOS promoter, and a role for hypoxia and Hif-1 protein in human iNOS transcription has not been described. Likewise, NF-IL6 (i.e., CAAT/EBP) and Brn3 proteins and promoter elements have been localized in the murine promoter, and it is not yet known whether these promoter elements participate in the regulation of human iNOS transcription. Conversely, a complex role for AP-1 proteins has been described for the human system, and functional AP-1 binding sites have been identified only in the human promoter. It should be recognized that the precise signal transduction pathways and molecular interactions by which the extracellular signals are conveyed to the nuclear transcription machinery are very active topics of many investigations.

sone inhibits cytokine-induced iNOS mRNA in human A549 epithelial cells by downregulating nuclear NF- κ B DNA-binding activity without an increase in I κ B α mRNA levels, and they suggested a glucocorticoid receptor–NF κ B protein–protein interaction (Kleinert *et al.*, 1996a). Our group reported that dexamethasone decreased iNOS mRNA levels in rat hepatocytes and that this downregulation occurred at the level of transcription (de Vera *et al.*, 1997). This effect is a result of increased cytosolic I κ B α levels and a concomitant decrease in nuclear p65 translocation in the presence of dexamethasone. In human colon carcinoma DLD-1 cells, Salzman reported that dexamethasone exhibited only a slight decrease in iNOS mRNA expression (Salzman *et al.*, 1996), and Kleinert found no inhibition of iNOS mRNA levels by dexamethasone in the same DLD-1 cells (Kleinert *et al.*, 1998). Perrella found that dexamethasone decreased iNOS mRNA levels in rat aortic vascular smooth muscle cells only when given before IL-1 β and not after (Perrella *et al.*, 1994). In contrast, Kunz reported that dexamethasone did not alter IL-1 β -induced iNOS mRNA in rat mesangial cells. Surprisingly, nuclear run-on experiments showed that dexamethasone markedly attenuated IL-1 β -induced iNOS gene transcription, and this was counteracted by a prolongation in iNOS mRNA half-life from 1 to 2.5 hours (Kunz *et al.*, 1996). In RAW 264.7 cells, dexamethasone inhibited the IFN γ -induced expression of both iNOS mRNA and protein. The inhibition resulted from a reduced level of mRNA transcription, lessened mRNA stability, decreased mRNA translation, and an increase in calpain-mediated proteolysis of iNOS protein (Walker *et al.*, 1997). A possible explanation for the cell type-specific differences in dexamethasone-mediated repression of cytokine-induced iNOS transcription would invoke that the glucocorticoid receptor and NF- κ B are in competition for limiting amounts of the general transcription coactivator CBP/p300 (Sheppard *et al.*, 1998). The observed differences could relate to various outcomes of the competition for CBP/p300, as well as to cell type differences in the regulation of iNOS mRNA half-life, translation, and protein stability. Despite extensive clinical use of glucocorticoids as immunosuppressive agents in patients with autoimmune diseases or after organ transplants, we have only begun to understand the mechanisms by which these drugs elicit their anti-inflammatory actions. Downregulation of iNOS expression during inflammation is one way by which steroids may exert their therapeutic effects.

A large variety of agents have been shown both to reduce cytokine-induced NF- κ B activation and to inhibit cytokine-induced iNOS transcription. Important biological inhibitors of NF- κ B activation and iNOS expression include cAMP-elevating agents (Mustafa and Olson, 1998; Pahan *et al.*, 1997; Parry and Mackman, 1997), steroids (Miller *et al.*, 1996), atrial natriuretic peptide (Kierner and Vollmar, 1998), melatonin (Gilad *et al.*, 1998), the PPAR receptor (Ricote *et al.*, 1998), and IL-11 (Trepicchio *et al.*, 1997). Important environmental or pharmacological inhibitors of both NF- κ B activation and iNOS expression include heat shock (de Vera

et al., 1996b; Feinstein *et al.*, 1996), reactive oxygen species scavengers (de Vera *et al.*, 1996b; Feinstein *et al.*, 1996; Liu *et al.*, 1997; Mulsch *et al.*, 1993; M. P. Sherman *et al.*, 1993), calcineurin inhibitors (Kunz *et al.*, 1995; Muhl *et al.*, 1993), aspirin (Farivar and Brecher, 1996), and cannabinoids (Jeon *et al.*, 1996). However, the manner in which the various agents inhibit the activation of NF- κ B is unknown.

Transforming growth factor β (TGF- β) also partially prevents induced NO synthesis. Suppression of iNOS expression by TGF- β *in vitro* has been shown in macrophages (Ding *et al.*, 1990), mesangial cells (Pfeilschifter and Vosbeck, 1991), and cardiac myocytes (Roberts *et al.*, 1992). In rat aortic smooth muscle cells, TGF- β decreased IL-1 β -stimulated iNOS mRNA by decreasing iNOS transcription (Perrella *et al.*, 1994) and promoter activity (Perrella *et al.*, 1996). On the basis of studies in primary murine macrophages, Vodovotz reported that this inhibition occurred at the posttranscriptional level and not by a direct effect on transcription: TGF- β suppressed macrophage iNOS expression by decreasing iNOS mRNA stability and translational efficiency, and by decreasing stability of iNOS protein (Vodovotz *et al.*, 1993). TGF- β inhibited induced NO synthesis in murine HC (77%), rat HC (17%), and human HC (10%), highlighting the significant variation between species (Nusler *et al.*, 1995). Interestingly, TGF- β actually enhances induction of iNOS mRNA in Swiss 3T3 fibroblasts (Gilbert and Herschman, 1993; Kleinert *et al.*, 1996b) and human keratinocytes (Arany *et al.*, 1996). Importantly, the expression of iNOS mRNA and protein are increased in the heart and kidney of the TGF- β null mouse, and retinal pigmented epithelium expresses higher levels of iNOS mRNA and protein in response to LPS plus IFN γ (Vodovotz *et al.*, 1996a,b). Furthermore, transgenic mice engineered to overexpress TGF- β from an albumin promoter display decreased serum nitrite/nitrate and decreased cytokine-induced iNOS mRNA and protein in peritoneal macrophages. Paradoxically, these same mice show increased iNOS mRNA and protein expression in the liver and kidney (Vodovotz *et al.*, 1998). These results underscore the complexity of iNOS regulation and lend support to the notion that species- and cell-specific mechanisms are likely to be important in controlling iNOS expression.

Similar to the feedback regulation of many cellular mediators, NO has been shown to exert a negative regulatory effect on iNOS gene expression (Colasanti *et al.*, 1995; Gris-cavage *et al.*, 1993; Park *et al.*, 1997; Peng *et al.*, 1995; Taylor *et al.*, 1997). Taylor demonstrated that addition of the NO donor *S*-nitroso-*N*-acetyl-D,L-penicillamine (SNAP) markedly decreased steady-state iNOS mRNA and protein levels in rat and human hepatocytes. Nuclear run-on analysis revealed that SNAP inhibited CM-stimulated iNOS gene transcription by 80%, whereas gel shift assays of the nuclear extracts revealed that SNAP decreased CM-induced DNA-binding activity for NF- κ B in a concentration-dependent manner. These studies identify a negative feedback loop whereby NO downregulates iNOS gene expression, possibly

to limit overproduction during pathophysiological conditions. Ignarro's group has shown that NO can also inhibit iNOS enzyme activity (Griscavage *et al.*, 1993), indicating another level of negative feedback regulation for posttranslational control of induced NO synthesis.

The tumor suppressor protein p53 encodes an important nuclear transcription factor that is induced in response to a variety of environmental and biological stressors, including exogenous mutagenic agents. Importantly, the p53 gene is mutated in up to 50% of all human cancers. Intriguingly, a variety of human cancer cell lines are shown to constitutively express high levels of iNOS, suggesting that p53 is a repressor of iNOS expression (Ambs *et al.*, 1997, 1998a). As NO has been shown to be mutagenic (Wink *et al.*, 1991), it was hypothesized that NO donors would induce p53 expression. Exposure of human cells to a NO donor resulted in nuclear p53 accumulation. Furthermore, overexpression of wild-type but not mutant p53 resulted in downregulation of iNOS transcription in a variety of human and rodent cells (Forrester *et al.*, 1996). These data imply a novel negative feedback loop where NO-induced DNA damage activates p53 expression which then *trans*-represses iNOS transcription, functioning as a safeguard against NO-induced DNA damage. As a follow-up to this *in vitro* study, the relationship between iNOS and p53 was examined *in vivo* in cancer-prone p53 knockout mice. Untreated p53 knockout mice excreted 70% more urinary nitrate than wild-type controls, and iNOS protein expression was constitutively detected only in the spleen of knockout mice and not in the spleens of wild-type mice. Following *C. parvum* injection, urinary nitrate excretion in the knockout mice exceeded that of the wild-type controls by 200% (Ambs *et al.*, 1998b). These data corroborate the *in vitro* findings and indicate that p53 is an important *trans*-repressor of basal and stimulated iNOS expression *in vivo*. The ability of p53 to repress iNOS transcription has been mapped in promoter-reporter experiments to the proximal iNOS promoter in the vicinity of the TATA box (Forrester *et al.*, 1996). Importantly, it has been reported that p53 can repress basal and activated transcription through direct physical interactions with the TATA box binding protein (TBP) (Farmer *et al.*, 1996; Liu *et al.*, 1993; Seto *et al.*, 1992; Thut *et al.*, 1997). Intriguingly, p53 can also compete against p65 NF- κ B for limiting amounts of the general transcription coactivator, CBP/p300 (Ravi *et al.*, 1998).

Mechanisms involved in the "activation" of iNOS transcription may function in part by altering repressive chromatin structures as well as in the direct "activation" of transcription mediated by interactions with the general transcription machinery. Reorganization of chromatin during the expression of HIV has been shown to involve NF- κ B sequences in the HIV long terminal repeat, and NF- κ B-dependent chromatin reorganization has been described using *in vitro* (Pazin *et al.*, 1996; Steger and Workman, 1997; Widlak *et al.*, 1997) and *in vivo* footprinting technology (Demarchi *et al.*, 1996). The factors that function in the establishment of repressive chromatin structures have not been

described, although it should be noted that HMG-I (Y) protein is an architectural component of chromatin and that many HMG proteins are repressive to basal transcription (Stelzer *et al.*, 1994). HMG proteins can either block or facilitate the DNA binding and/or the *trans*-activating potentials of other transcription factors including both NF- κ B and ATF transcription factors (Du and Maniatis, 1994; Lehming *et al.*, 1994; Lewis *et al.*, 1994; Munshi *et al.*, 1998; Thanos and Maniatis, 1992). Recently, an AT-rich HMG-I (Y) DNA binding element has been localized at -61 to -54 in the mouse promoter just downstream of the -85 to -76 NF- κ B sequence and overlapping with the Oct/Brn3A element that is important for iNOS promoter reporter activation by LPS and IL-1 β . Furthermore, HMG-I (Y) and p50 NF- κ B were observed in a ternary complex with DNA in gel shift assays. Overexpression of HMG-I has been shown to potentiate activation of the iNOS promoter by transfected p50 or p65 NF- κ B expression plasmids (Perrella *et al.*, 1999). These data demonstrate functional cooperation between NF- κ B and HMG-I (Y) for iNOS induction and highlight that transcription factors function in the context of an ill-defined nucleoprotein environment.

Many of the biological and pharmacological agents that exert a negative effect on iNOS expression have been shown to reduce the activation of either NF- κ B, Stat1, or IRF-1 as described previously. However, a variety of other agents, including hormones (Miller *et al.*, 1996), growth factors (Goureau *et al.*, 1993; Heck *et al.*, 1992; Kunz *et al.*, 1997; Liu *et al.*, 1996; Schini *et al.*, 1994), and cytokines (Bogdan *et al.*, 1994; Cunha *et al.*, 1992; Sands *et al.*, 1994), can inhibit the expression of iNOS mRNA through mechanisms that have not been described. Recent data indicate the involvement of the phosphatidylinositol-3-kinase (PI-3-kinase) in the inhibitory regulation of iNOS by either IL-13 (Doyle *et al.*, 1994; Wright *et al.*, 1997) or macrophage stimulating protein (MSP) activation of the RON receptor tyrosine kinase (Chen *et al.*, 1998). However, the downstream target(s) of PI-3-kinase that mediates the negative regulation of iNOS expression is not defined. Moreover, other data indicate functional interactions between a variety of cell surface receptors including the IL-4 and IL-13 receptors and the tyrosine phosphatases SHP-1 and SHP-2, which also interact with and dephosphorylate the PI-3-kinase (Gesbert *et al.*, 1998; Imani *et al.*, 1997; Yu *et al.*, 1998). Other data indicate that IL-1, IGF-II, or hypoxia can activate NF- κ B downstream of the PI-3-kinase (Kaliman *et al.*, 1999; Sands *et al.*, 1994; Sizemore *et al.*, 1999), possibly by phosphorylating and activating the *trans*-activation domain of NF- κ B p65 (Sizemore *et al.*, 1999). Importantly, SHP-1 is also a negative regulator of NF- κ B activation (Massa and Wu, 1998). These data suggest the possibility that IL-4, IL-10, and IL-13 may negatively regulate NF- κ B activity by dephosphorylation of PI-3-kinase mediated by SHP-1 or SHP-2, serving to limit the *trans*-activation potential of NF- κ B. Intriguingly, SHP-1 (Imani *et al.*, 1997; Ram and Waxman, 1997; You and Zhao, 1997; Yu *et al.*, 1998) or SHP-2 (Gesbert *et al.*, 1998; Servidei *et al.*, 1998; Yin *et al.*, 1997; You *et al.*, 1999)

are also negative regulators of the IFN- γ -Jak-Stat pathway, suggesting that SHP proteins may negatively regulate the NF- κ B pathway through the dephosphorylation of PI-3-kinase, and the IFN- γ -Jak-Stat pathway by dephosphorylation of Jak and/or Stat proteins.

Posttranscriptional Regulation of iNOS Expression

In addition to transcriptional control, posttranscriptional regulation of the iNOS gene has been identified. As already mentioned, TGF- β suppresses macrophage iNOS expression by posttranscriptional mechanisms (Vodovotz *et al.*, 1993). Whereas dexamethasone decreases iNOS transcription, it has also been shown to exert posttranscriptional effects by increasing iNOS mRNA stability in IL-1 β -stimulated rat mesangial cells and vascular smooth muscle cells (Kunz *et al.*, 1996; Perrella *et al.*, 1994) and to increase calpain-like proteolysis of iNOS protein in RAW 246.7 macrophages (Walker *et al.*, 1997). The precise mechanisms for these posttranscriptional effects have not been elucidated. The 3'-untranslated region (UTR) of the human and rodent iNOS cDNAs contains several AT-rich sequences that correspond to the AU sequences in the mRNA (Geller *et al.*, 1993a). These ATTTA sequence motifs have been shown in many labile cytokine and protooncogene transcripts and have been shown to destabilize mRNA (Caput *et al.*, 1986; Shaw and Kamen, 1986) and inhibit translational efficiency (Han *et al.*, 1990). Nunokawa demonstrated a cooperative interaction between the 5'-promoter and the 3'-region of the human iNOS gene using luciferase promoter constructs containing both the iNOS 5'-flanking region and the 3'-UTR (Nunokawa *et al.*, 1997). Transfection of the constructs containing both the 5'- and 3'-regions resulted in a decrease in constitutive reporter gene activity and an increase in cytokine responsiveness.

Recently, Luss and co-workers cloned and characterized the expression of iNOS in human cardiac myocytes (Luss *et al.*, 1995). The human cardiac myocyte iNOS cDNA is >99% identical to the human hepatocyte iNOS cDNA that was previously cloned. Interestingly, although Luss *et al.* (1995) readily detected iNOS mRNA in cytokine-stimulated myocytes, they were unable to detect iNOS protein or NO synthesis. These data suggest that a translational defect exists for expression of iNOS in human cardiac myocytes, implying that cell-specific posttranscriptional mechanisms may be operating here. Whether this observation reflects rapid degradation of iNOS mRNA or a block in translational machinery has not been established.

Chu and colleagues have identified structural diversity in the 5'-UTR of the human iNOS gene. Despite the presence of a TATA box in the promoter, multiple transcription initiation sites were observed in ~6% of iNOS mRNAs expressed in cytokine-stimulated human A549 lung epithelial cells (Chu *et al.*, 1995). The TATA-independent iNOS mRNAs were also upregulated by cytokines. Alternative splicing in the 5'-UTR also accounted for further structural diversity

owing to the presence of eight partially overlapping open reading frames (ORFs) upstream from the major iNOS ATG. These ORFs may or may not have an important role in the translational regulation of the human iNOS mRNA.

In addition to alternative splicing in the 5'-UTR, Eissa *et al.* (1996) identified alternative mRNA splicing within the human iNOS mRNA. Four alternative mRNA transcripts were seen with internal deletions of exon 5, exons 8 and 9, exons 9–11, and exons 15 and 16. The deletion of exon 5 resulted in a truncated protein, whereas the other three variants produced in-frame deletions. Interestingly, expression of the exon 8–9⁺ iNOS cDNA in a human cell line produced iNOS protein that lacked functional NOS activity and did not result in production of NO (Eissa *et al.*, 1998). The molecular basis for this observation was the lack of iNOS protein dimerization as a result of the deleted exons, indicating a critical role of the exon 8–9 region for iNOS protein dimerization.

Molecular Control of Endothelial Derived Nitric Oxide

A New Paradigm for Endothelial NOS Regulation by Posttranslational Modifications

Jean-Philippe Gratton,* Jason Fontana,* and William C. Sessa

Department of Pharmacology and Molecular Cardiology Program

Boyer Center for Molecular Medicine

Yale University School of Medicine, New Haven, Connecticut

REGULATION OF ENDOTHELIUM-DERIVED NITRIC OXIDE (NO) PRODUCTION IS AN IMPORTANT AREA OF RESEARCH RELEVANT TO VARIOUS ASPECTS OF VASCULAR BIOLOGY INCLUDING VASOMOTOR CONTROL, THROMBOSIS, INFLAMMATION, VASCULAR REMODELING, AND ANGIOGENESIS. THE PURPOSE OF THIS CHAPTER IS TO HIGHLIGHT RECENT DEVELOPMENTS IN THE FIELD OF ENDOTHELIAL NITRIC OXIDE SYNTHASE REGULATION BY POSTTRANSLATIONAL CONTROL MECHANISMS AS THEY PERTAIN TO BOTH BASAL AND STIMULATED PRODUCTION OF NO.

Introduction

The physiological production of nitric oxide (NO) by the vascular endothelium is important for cardiovascular homeostasis. NO synthesized by the nitric oxide synthase (NOS) family member, endothelial NOS (eNOS or NOS3), is the enzyme that produces endothelium-derived relaxing factor, identified as NO as originally demonstrated by the classic studies of Furchgott, Ignarro, and Moncada (Furchgott and Zawadzki, 1981; Ignarro *et al.*, 1987; Palmer *et al.*, 1987). eNOS-derived NO is important for blood pressure control, angiogenesis, and vascular remodeling as demonstrated by the profound perturbations in these processes in mice defi-

cient in this NOS isoform (Huang *et al.*, 1995; Murohara *et al.*, 1998; Rudic *et al.*, 1998). The purpose of this chapter is to highlight recent developments emerging in the area of eNOS regulation by posttranslational control mechanisms including fatty acylation, protein–protein interactions, and phosphorylation.

eNOS Fatty Acylation

N-Myristoylation

eNOS is unique among the NOS family of proteins due to the presence of an N-myristoylation consensus sequence elucidated from the cloning of its cDNA (Janssens *et al.*, 1992; Lamas *et al.*, 1992; Marsden *et al.*, 1992; Nishida *et*

*These authors contributed equally to this chapter.

al., 1992; Sessa *et al.*, 1992). The presence of glycine 2 (Gly-2) and serine 6 (Ser-6) in bovine and human eNOS conforms to the preferred substrate specificity for *N*-myristoyltransferase (Gordon *et al.*, 1991). Different studies investigating this premise, through metabolic labeling and site-directed mutagenesis of Gly-2, confirmed that native eNOS is able to incorporate [³H]myristic acid and that mutation of Gly-2 to an alanine (G2A mutation) converts the membrane-associated eNOS to a cytosolic form (Busconi and Michel, 1993; Liu and Sessa, 1994; Pollock *et al.*, 1992; Sessa *et al.*, 1993). The precise membrane compartments in which eNOS resides are controversial, but a majority of studies by several independent groups have shown that a large portion of membrane-associated eNOS is found on the Golgi complex in endothelial cells or cells stably transfected with the eNOS cDNA (Garcia-Cardena *et al.*, 1996a; Rizzo *et al.*, 1998; Sessa *et al.*, 1995; Stanboli and Morin, 1994). In transfected HEK 293 cells, wild-type eNOS localizes to the Golgi complex and produces ample quantities of NO, whereas cell lines expressing G2AeNOS, which is cytoplasmically distributed, are poor releasers of NO (Sessa *et al.*, 1995). This study was the first to suggest that compartmentalization of eNOS is important for the fidelity of stimulus-dependent NO release from cells. Interestingly, the kinetics of wild-type and G2A eNOS are identical both in cell lysates (Sessa *et al.*, 1993, 1995) and after purification to homogeneity (Venema *et al.*, 1995), in support of the idea that *N*-myristoylation is important for targeting but not the catalytic function of the enzyme.

Palmitoylation

On the basis of models with *N*-myristoylated peptides and certain lipids, it appears as if *N*-myristoylation per se is not sufficient to stably anchor proteins to biological membranes (Peitzsch and McLaughlin, 1993). This is supported by the observations that several *N*-myristoylated proteins are found in the cytosolic fractions of cells (Gordon *et al.*, 1991). High-salt treatment or membrane denaturation failed to release eNOS from the membrane fraction of endothelial cells (Busconi and Michel, 1994; Pollock *et al.*, 1991), suggesting that the association of eNOS with membranes be mainly due to strong hydrophobic interactions. Therefore, we and others suspected that additional modifications must be involved to keep eNOS tightly embedded in membranes. Posttranslational palmitate incorporation on cysteine residues of proteins, by the enzyme palmitoyltransferase, increases the hydrophobic properties of some proteins, thus facilitating stronger interactions with lipid bilayers (Resh, 1994). Using metabolic labeling and V8 protease digestion of labeled eNOS, we demonstrated that eNOS is palmitoylated on cysteine-15 and cysteine-26 (Liu *et al.*, 1995), and mutation of either cysteines reduced [³H]palmitic acid incorporation (by 95%) into eNOS, suggesting that palmitoylation of either cysteine is highly dependent on the presence of the other. However, it is controversial whether palmitoylation of eNOS

will influence its overall ability to interact with membranes. In our laboratory, palmitate incorporation is not necessary for membrane association of eNOS as the enzyme localizes in the membrane fractions following mutation of both cysteine-15 and cysteine-26 to serine (C15/26S eNOS). In addition, treatment of wild type versus palmitoylation mutants of eNOS with high ionic strength, high pH, or phase solubilization with Triton X-114 (a way to examine protein hydrophobicity) does not change the association of eNOS with membranes. However, another group has demonstrated that palmitoylation mutants of eNOS can partition slightly better into the cytosol, suggesting that palmitate did influence the overall hydrophobic character of the protein (Robinson and Michel, 1995). Regardless of these inconsistencies, both groups have shown that *N*-myristoylation must precede cysteine palmitoylation. Utilizing a different approach with various deletion mutants of eNOS coupled to the green fluorescent protein (GFP), *N*-myristoylation without palmitoylation does permit eNOS to interact with biological membranes and results in a diffuse perinuclear membrane appearance of the protein (Liu *et al.*, 1997). Identical results were obtained with C15/26S palmitoylation deficient eNOS-GFP and mutations that change the pentameric glycine-leucine repeat between the palmitoylation sites.

Palmitoylation is a reversible process, unlike *N*-myristoylation (Gordon *et al.*, 1991). The basal turnover of palmitate on eNOS is 45 min, while the turnover of myristate and the protein are close to 18–20 hours (Liu *et al.*, 1995). There is evidence that palmitoylation and depalmitoylation of proteins can be regulated by extracellular signals providing a mechanism for the dynamic regulation of protein localization (Degtyarev *et al.*, 1993; James and Olson, 1989; Mumby *et al.*, 1994; Wedegaertner and Bourne, 1994) however, this is a controversial area due to the lack of consensus demonstrating that palmitoylation (of G-protein α subunits, and/or src family members) really influences protein hydrophobicity (Huang *et al.*, 1999). The controversy spills into the NOS field since different groups have reported discrepant findings. One group has demonstrated that bradykinin and calcium ionophore stimulation of endothelial cells induces the depalmitoylation of eNOS (Robinson *et al.*, 1995), resulting in its translocation from the membrane to the cytosol; however this result was not shown by other groups who have documented that agonists cause an increase in calcium, NO release, and eNOS phosphorylation (Liu *et al.*, 1995; D. G. Harrison, personal communication) with no effect on the rate of palmitoylation and depalmitoylation. So if palmitoylation of eNOS does not influence the catalytic activity or overall hydrophobicity, then what is its role? Two groups independently reported that palmitoylation of eNOS is necessary for targeting of eNOS to specific plasmalemmal domains called caveolae (Garcia-Cardena *et al.*, 1996a; Shaul *et al.*, 1996). We will discuss in the following sections the importance of eNOS localization into caveolae microdomains.

eNOS Trafficking into Caveolae

Caveolin and Caveolae

Caveolae are small, specialized cholesterol- and sphingolipid-rich invaginations of the plasma membrane. They are similar in composition to lipid rafts, which can be a target for GPI linked or fatty acylated proteins. Caveolae are present in most eukaryotic cell types and are abundantly found in capillary endothelium, vascular smooth muscle, fibroblasts, and adipocytes (Okamoto *et al.*, 1998). These specialized membrane domains have been implicated in transcytosis of macromolecules (Schnitzer *et al.*, 1994), in potocytosis (Anderson, 1993), and in signal transduction (Lisanti *et al.*, 1994).

The major structural protein of caveolae is caveolin, a 21- to 24-kDa integral membrane protein which, at first, received attention as a tyrosine phosphorylated substrate of the Rous sarcoma viral oncogene on cellular transformation and was subsequently shown to be associated with cell caveolae (Glenney and Soppet, 1992; Kurzchalia *et al.*, 1992; Rothberg *et al.*, 1992). Caveolin expression corresponds to some extent with caveola formation, furthermore cell lines that do not express caveolin, such as lymphocytes and neuroblastoma cells, appear to function without detectable number of caveolae presumably due to lipid rafts which may subserve a similar functional role (Fra *et al.*, 1994; Gorodinsky and Harris, 1995). The caveolin family comprises three isoforms, caveolin-1, -2, and -3, that show general similarity in structure and function but differ in specific properties and tissue distribution. Two isoforms of caveolin-1, α and β , are derived from alternate initiator codons during translation. Caveolin-3 shows a muscle specific tissue distribution (e.g., skeletal muscle and myocytes) and may replace caveolin-1 as the major caveolar protein of differentiated muscle cells (Way and Parton, 1995). Caveolin-1 and caveolin-2 are abundantly expressed in adipocytes, endothelial cells, and fibroblastic cell types. They also colocalize in the cell and may form a stable hetero-oligomeric complex *in vivo* (Scherer *et al.*, 1997).

The amino and carboxyl termini of caveolin are cytoplasmic and are flanked by an unusual 33-amino acid putative transmembrane domain. Caveolin also possess multiple palmitoylation sites at the carboxyl-terminal end. The role of caveolin in caveolar formation may be related to the self-assembly properties of caveolin-1. Firstly, in the endoplasmic reticulum, caveolin-1 monomers assemble into homo-oligomers (14–16 monomers per oligomers). Subsequently, these oligomers can interact with each other to form clusters of particles of 25–50 nm in diameter. Finally, these oligomers can specifically interact with glycosphingolipids and cholesterol, and they require a high cholesterol content to insert themselves into lipid membranes. Thus, through the interaction of caveolin-1 with itself and the selectivity of caveolin for the endogenous lipid component of the membrane, a caveola vesicle may be generated (Li *et al.*, 1996).

eNOS Localization in Caveolae

A fraction of eNOS has been shown to reside in a Triton X-100 insoluble fraction of endothelial cell lysates. Triton X-100 insolubility of proteins has been considered as a marker of both cytoskeletal proteins and, more recently, proteins residing in caveolae and other glycolipid-rich domains (Garcia-Cardena *et al.*, 1996a). Using the low buoyant properties of these microdomains, purification of caveolae has been achieved by different fractionation techniques. This has allowed different laboratories to show that the caveolae are enriched by many signaling molecules, including components of the Ras-extracellular signal-related kinase (ERK) pathway (Anderson, 1998; Oh and Schnitzer, 1999; Smart *et al.*, 1995). Interestingly, many of the proteins shown to be present in plasmalemmal caveolae are, like eNOS, dually acylated. Using the previously mentioned techniques and purification of luminal caveolae with colloidal silica, it was shown that eNOS is enriched in the caveola fractions of endothelial cells (Garcia-Cardena *et al.*, 1996a; Shaul *et al.*, 1996). Furthermore, immunolabeling and electron microscopy studies have shown that some of eNOS colocalizes with caveolin-1 and in caveolae (Garcia-Cardena *et al.*, 1996a; Rizzo *et al.*, 1998; Shaul *et al.*, 1996). The absolute amount of eNOS in caveolae may vary within vascular beds (Andries *et al.*, 1998), between species, or change with the passage or confluency state of the endothelial cells in culture (Sowa *et al.*, 1999).

The targeting of eNOS to caveolae is dependent on cysteine palmitoylation of eNOS. Mutation of the cysteine palmitoylation sites markedly reduces its targeting to the plasma membrane and caveolae (Garcia-Cardena *et al.*, 1996a; Shaul *et al.*, 1996; Sowa *et al.*, 1999) and stimulated NO release from stably transfected HEK cells (Liu *et al.*, 1996), suggesting that palmitoylation is a “molecular zip code” for the trafficking of eNOS into glycolipid-rich microdomains of the plasmalemma and for efficient NO release. Interestingly, a study using fluorescent recovery after photobleaching (FRAP) of eNOS-GFP in living cells has demonstrated that the trafficking rates of eNOS-GFP differ in Golgi versus plasma membrane suggesting that each pool of enzyme may uniquely interact organelle specific proteins that determine its rate of movement (Sowa *et al.*, 1999). In cells expressing palmitoylation mutant eNOS-GFP, the protein is diffusely distributed in the perinuclear region of cells, does not move into intercellular apical junctions, and has a much faster rate of movement compared to wild-type NOS in the Golgi and plasma membrane. These data support the ideas that (1) palmitoylation is a targeting motif for eNOS and (2) that palmitoylation can kinetically slow down the rate of protein movement in cellular microdomains.

eNOS Interactions with Caveolin

Caveolin, being the major coat protein of caveolae, has the capacity to directly interact with other intracellular pro-

teins such as c-Src and Ha-Ras through amino acids 82–101, the putative scaffolding domain (Okamoto *et al.*, 1998). Indeed, three groups have independently demonstrated that eNOS could directly interact with caveolin-1 or caveolin-3 (Feron *et al.*, 1996; Garcia-Cardena *et al.*, 1996b, 1997; Ju *et al.*, 1997). Mapping of the eNOS binding site in caveolin was studied by the usage of recombinant GST–caveolin fusion proteins. The primary binding region of caveolin-1 for eNOS is within amino acids 60–101 and to a lesser extent within amino acids 135–178 (Garcia-Cardena *et al.*, 1997; Ju *et al.*, 1997). These results were also obtained in a yeast two-hybrid system where the different domains of eNOS and caveolin-1 were expressed (Ju *et al.*, 1997). Furthermore, the caveolin–eNOS immunocomplex is disrupted in presence of caveolin scaffolding peptides (Michel *et al.*, 1997a).

In order to determine what is the preferred and specific binding motif for proteins that can interact with caveolin-1, Couet *et al.* (1997) used a phage display library and found a consensus caveolin binding sequence. This sequence is rich in aromatic residues with specific spacing between each of them, and the motifs $\phi\chi\chi\phi\chi\chi\chi\phi$, $\phi\chi\chi\chi\chi\phi\chi\chi\phi$, and $\phi\chi\phi\chi\chi\chi\phi\chi\chi\phi$ (where ϕ represents either Trp, Phe, or Tyr and χ represents any amino acid) were shown to bind the caveolin scaffolding domain. Interestingly, these motifs are present in most known caveolin-interacting proteins and were shown to be important for specific caveolin interactions (Couet *et al.*, 1997). eNOS contains one of these particular caveolin-binding sequences (**Phe-Ser-Ala-Ala-Pro-Phe-Ser-Glu-Trp**) located within amino acids 350–358.

Importance of the caveolin interaction with eNOS has been most reproducibly demonstrated by the effects of caveolin scaffolding peptides and GST–caveolin on NOS activity. Incubation of pure eNOS with peptides derived from the scaffolding domains of caveolin-1 and -3 resulted in inhibition of eNOS activity (Garcia-Cardena *et al.*, 1997). In co-transfection experiments, caveolin overexpression in COS-7 cells resulted in a reduction of eNOS activity (Michel *et al.*, 1997b), and a reduction in NO release was also observed (Garcia-Cardena *et al.*, 1997). Furthermore, site-directed mutagenesis of the predicted caveolin binding motif within eNOS blocked the ability of caveolin to suppress NO release in the latter experiments (Garcia-Cardena *et al.*, 1997). The reduction of eNOS activity by caveolin peptides, or overexpressed caveolin, is reversed by exogenous addition of calmodulin, suggesting a reciprocal regulation of eNOS by calmodulin, an activator, and caveolin, an inhibitor (Feron *et al.*, 1998a,b; Michel *et al.*, 1997a,b). This dual regulation of eNOS by these two proteins has also been shown in terms of protein interactions *in vitro*. The coimmunoprecipitation of the eNOS/caveolin-1 complex is favored in absence of calcium and reduced by addition of calcium–calmodulin. Stimulation of cells by calcium-dependent agonists and calcium ionophores results in a reduced eNOS–caveolin interaction. However, the prolonged time frame used to demonstrate these reciprocal interactions are not consistent with NO release from cells.

Collectively, these overall results suggest that NO production is negatively regulated by interactions with caveolin and that for NO release to occur, the inhibitory clamp by caveolin must be overcome. Calmodulin (CaM) has been proposed to be solely responsible for the dissociation of eNOS from caveolin. However, the relationship between caveolin as an inhibitor of eNOS and CaM as its allosteric modulator have not been examined in light of new findings demonstrating a role for heat-shock protein 90 (hsp90) and protein phosphorylation as regulator of eNOS activation (see below). It remains to be confirmed if activation of eNOS implies dissociation from caveolin; that is, the inhibitory action might be overcome without any physical dissociation of the eNOS from caveolin or caveolae, particularly during calcium-independent stimulation of NO release elicited by prolonged shear stress (Rizzo *et al.*, 1998). There is no direct evidence to date showing that disruption of the eNOS–caveolin complex can lead to increased NO release from cells, a fundamental experiment if caveolin-1 truly regulates eNOS and NO release. The observed dissociation of caveolin and eNOS following stimulation of endothelial cells by calcium mobilizing agonists, may be a consequence of eNOS activation rather than removal of an inhibitory clamp on eNOS activity. However, there is a recent report demonstrating that loading of cells with low density lipoprotein (LDL)–cholesterol increases caveolin-1 expression and its interaction with eNOS, thereby dampening agonist stimulated NO release (Feron *et al.*, 1999) but another report shows no effects of cholesterol loading on caveolin-1 levels, but increases in eNOS protein levels (Peterson *et al.*, 1999). In this latter study, the fractionation of eNOS into caveolin-enriched domains is enhanced whereas agonist-induced NO release is not effected (Peterson *et al.*, 1999). The interactions of eNOS with other activating proteins such as hsp90 or after phosphorylation might allow us to better understand the regulatory cycle of basal versus stimulated NO release and the additional roles of caveolin in NO biosynthesis.

hsp90 and eNOS

As discussed previously, eNOS is negatively regulated by a direct interaction with caveolin. However, more recent work has identified a positive regulator of eNOS, hsp90 (Garcia-Cardena *et al.*, 1998).

hsp90

The hsp90 family is a group of highly conserved stress proteins that are expressed in all eukaryotic cells (Pratt, 1997). Two genes encode hsp90, with the human gene products hsp90 α and hsp90 β having 86% sequence homology. Hsp90 is highly abundant in cells, accounting for 1–2% of cytosolic protein, and it is localized to the cytoplasm, with a small amount found in the nucleus (Czar *et al.*, 1996; Pratt, 1997). The main function of hsp90 has been its involvement

in a multicomponent chaperone system that is responsible for the proper folding of proteins such as steroid receptors and cell-cycle dependent kinases (Buchner, 1999). However, the abundance of hsp90 associated with signaling proteins suggests that this may not be its only function. There is increasing evidence that hsp90 may be an integral part of signal transduction in all cells.

hsp90 Involvement in Signal Transduction

A variety of peripheral membrane signaling proteins including v-Src (Oppermann *et al.*, 1981), Raf-1 (Stancato *et al.*, 1993), MEK (Stancato *et al.*, 1997), and G-protein $\beta\gamma$ (Inanobe *et al.*, 1994) can exist in heteromeric complexes with hsp90. Genetic studies in both *Drosophila melanogaster* and *Saccharomyces cerevisiae* have demonstrated that hsp90 homologs are essential genes (Cutforth and Rubin, 1994; Nathan and Lindquist, 1995). In *Drosophila melanogaster* (Cutforth and Rubin 1994), the hsp90 ortholog hsp83 is involved in mediating receptor tyrosine kinase signaling pathways, whereas in *Saccharomyces cerevisiae*, hsp82 is an integral component of reconstituted steroid receptor and v-Src-dependent signal transduction events (Nathan and Lindquist, 1995). Potential mechanisms to account for these effects include hsp90-mediated actions on protein folding, stability, and targeting of signaling proteins.

hsp90–eNOS Interaction

Previously we had shown that eNOS coprecipitated with a 90-kDa tyrosine phosphorylated protein (Garcia-Cardena *et al.*, 1998) and work by Venema *et al.* (1996) has demonstrated that bradykinin induced the recruitment of a 90-kDa protein to eNOS (Venema *et al.*, 1996). In metabolic labeling studies in our laboratory, immunoprecipitation of ^{35}S -labeled eNOS resulted in the coprecipitation of a 90-kDa protein (J.-P. Gratton, J. Fontana, and W. C. Sessa, unpublished). These findings, coupled with the cadre of exciting information linking hsp90 to signal transduction, prompted our investigation into whether hsp90 was associated with eNOS. Indeed, hsp90 was associated with eNOS in resting endothelial cells, and treatment of cells with three distinct stimuli that cause NO release [vascular endothelial growth factor (VEGF), histamine, and fluid shear stress] all enhanced the interaction between hsp90 and eNOS (Garcia-Cardena *et al.*, 1998). More importantly, VEGF or histamine stimulated the rapid recruitment of hsp90 to eNOS in endothelial cells in a time frame consistent with NO release. Fluid shear stress also caused the recruitment of hsp90 to eNOS, but the kinetics of the recruitment were slower with maximal recruitment at 1 hour.

To further study the relationship between hsp90-mediated signaling and NO production, a specific inhibitor of hsp90, the ansamycin antibiotic geldanamycin (GA), was used. Geldanamycin binds to the ATP site of hsp90 and influences the conformational stability of hsp90 binding to its substrates

(Stebbins *et al.*, 1997). Activation of protein kinases such as Raf-1 (Schulte *et al.*, 1995; Stancato *et al.*, 1997) and v-Src (Whitesell *et al.*, 1994) and facilitation of steroid hormone binding to nuclear receptors (Sullivan and Toft, 1993) are all signaling events dependent on hsp90 and are blocked by GA. Treatment of endothelial cells with GA attenuated histamine- and VEGF-stimulated cGMP production but did not influence the ability of the NO donor sodium nitroprusside to increase cGMP production, indicating that inhibition of agonist-induced NO release was due to inhibition of hsp90 signaling. To test the involvement of hsp90 in endothelium-dependent relaxations of isolated blood vessels, the influence of GA on acetylcholine (ACh)-induced relaxations of the rat aorta was examined. GA blocked ACh-induced vasorelaxation of rat aortic rings by greater than 70%, and these effects were reversible, as washout of GA restored ACh-induced vasorelaxation (Garcia-Cardena *et al.*, 1998). Collectively these data supported the idea that the rapid activation of hsp90 (perhaps via phosphorylation) and the subsequent binding to eNOS occurred on a time frame consistent with NO release.

Further support for the relevance of hsp90–eNOS interactions was demonstrated in a model of portal vein ligation (PVL) in rats (Shah *et al.*, 1999). In this study, the participation of hsp90 in the eNOS-dependent hyperresponsiveness in rat mesentery was examined. In normal animals eNOS and hsp90 were coassociated in extracts prepared from the mesenteric microcirculation and both eNOS and hsp90 localized to the endothelial lining of mesenteric vessels. In the perfused mesenteric vasculature of normal animals, GA attenuated ACh-dependent vasodilatation to the same extent as conventional NOS inhibitors. In portal hypertensive rats, eNOS protein levels are not changed compared to control rats, but NOS activity is markedly enhanced in the mesenteric tissue of hypertensive rats. The enhanced activity correlated with hyporesponsiveness to the vasoconstrictor methoxamine (MTX) in perfusion studies (Sieber *et al.*, 1992). Interestingly, GA potentiated the MTX-induced vasoconstriction after PVL, partially reversing the hyporeactivity to this agent, indicating that hsp90 can act as a signaling component leading to NO-dependent responses in the mesenteric microcirculation.

Potential Mechanisms for hsp90 Recruitment and Activation of eNOS

The evidence discussed earlier provides a great deal of support to the hypothesis that hsp90 associates with eNOS in a stimulus-dependent manner, and it suggests that hsp90 is necessary for both NO release and endothelium-dependent responses within intact blood vessels. However, the intracellular signaling pathways that lead to association of hsp90 and eNOS and the mechanism by which hsp90 is able to activate eNOS remain unresolved. The rapid stimulus-dependent formation of the hsp90–eNOS heteromeric complexes suggests that it occurs simultaneously with other

signaling events, such as the mobilization of intracellular calcium and/or protein phosphorylation. Calcium mobilization will lead to activation of calmodulin, a known NOS-interacting protein that may, in turn, influence the association of hsp90 and eNOS. The change in the state of phosphorylation of proteins in the VEGF signaling pathway may lead to activation of downstream effectors required for the hsp90–eNOS association. Also, a change in the phosphorylation state of hsp90 and eNOS themselves may result in a conformational change leading to increased association of the two. These possibilities are currently being examined.

When hsp 90 interacts with eNOS, how does this influence NO release? Previously we showed that hsp90 can directly activate eNOS *in vitro* (Garcia-Cardena *et al.*, 1998) and that coexpression of eNOS with hsp90 in COS cells increased NOS activity. These results suggest that hsp90 may act as an allosteric modulator of eNOS by inducing a conformational change in the enzyme, which results in increased activity or possibly stabilizes the complex. A paper by Bender *et al.* (1999) demonstrated that neuronal NOS (nNOS) could also interact with hsp90. In that paper, hsp90 is associated with nNOS in cells in which the nNOS protein is overexpressed, and the interaction was detected using lower stringency immunoprecipitation conditions than those used for eNOS/hsp90. Short-term treatment with GA of cells expressing nNOS decreased NO release, an effect not associated with a change in nNOS levels, whereas long-term treatment with GA reduced nNOS protein levels. In these experiments the authors could not demonstrate an effect of hsp90 on apo-nNOS reconstituted with heme; however, hsp90 did increase heme incorporation. Overall the authors concluded that if heme is rate limiting, hsp90 is required for sustained opening of the heme binding cleft in NOS; on the other hand, when heme is not the limiting factor, as in a cell-free system, hsp90 is not required (Bender *et al.*, 1999). This is an interesting idea and may be one of the ways hsp90 activates eNOS, but the findings do not completely coincide with the studies on hsp90 and eNOS. First, the kinetics of exogenous heme incorporation into nNOS is much slower than that of eNOS activation in response to VEGF. Second, hsp90 does influence eNOS conformation in order to increase its activity, but it remains to be seen if heme binding or stabilization is the only action that hsp90 exerts on eNOS.

eNOS Regulation by Protein Phosphorylation

Endothelial NOS can be phosphorylated on serine, tyrosine, and threonine residues. eNOS serine phosphorylation was originally described by Michel *et al.*, who demonstrated that different forms of stimuli such as bradykinin, ionomycin, and sodium nitroprusside can increase eNOS serine phosphorylation (Michel *et al.*, 1993). It was subsequently demonstrated that activation of protein kinase C increases eNOS serine phosphorylation (Hirata *et al.*, 1995; Ohara *et al.*, 1995). In addition, we demonstrated that eNOS is phos-

phorylated on both tyrosine and serine, an effect which is markedly enhanced by the tyrosine phosphatase inhibitor vanadium (Garcia-Cardena *et al.*, 1996b). In these experiments the documented increase in tyrosine phosphorylation was associated with a decrease in eNOS activity in immunoprecipitates. Phosphorylation of eNOS on serine, tyrosine, and threonine was demonstrated by Flemming *et al.* (1998). These authors also showed that fluid shear stress enhanced eNOS serine phosphorylation but reduced tyrosine phosphorylation, whereas Corson *et al.* (1996) showed that shear stress increased serine phosphorylation only, with no detectable levels of tyrosine phosphorylation. However, in all the above cases, the site(s) of phosphorylation was not described, nor was a direct physiological link between phosphorylation and eNOS activation established.

Previously it was shown that insulin- and VEGF-driven NO release from endothelial cells was partially attenuated by structurally distinct inhibitors of phosphatidylinositol 3-kinase (PI-3 kinase) (Papapetropoulos *et al.*, 1997; Zeng and Quon, 1996). These findings sparked our interest in examining the possible participation of downstream kinases in the activation of eNOS. One downstream effector of PI-3 kinase is the serine/threonine kinase, called protein kinase B or Akt (Downward, 1998; Franke *et al.*, 1997). On activation of growth factor receptors, G-protein-coupled receptors, or mechanotransduction, Akt is recruited to the plasma membrane (via its pleckstrin homology domain) and binds to PI-3-kinase generated inositol phospholipids {phosphatidylinositol 1,4,5-trisphosphate (PIP₃), phosphatidylinositol 3,4-bisphosphate [PI (3,4)P₂]}. Once in the plasma membrane, Akt is phosphorylated on threonine-308 (by the serine/threonine kinase PDK-1) and/or calmodulin dependent protein kinase kinase (CaMKK) and on serine-473 (by the serine/threonine kinase PDK2) resulting in its ability to phosphorylate and inhibit effectors such as the proapoptotic proteins, BAD and caspase-9 or influence cell metabolic pathways by phosphorylating phosphofructokinase (PFK) and glycogen synthase kinase (GSK).

To examine the relationship between Akt and eNOS, we examined if Akt overexpression could stimulate eNOS-derived NO production in a heterologous expression system (Fulton *et al.*, 1999). Indeed, this did occur by direct phosphorylation of serine-1179, *in vitro* and *in vivo*. Mutation of serine-1179 to alanine attenuated Akt-stimulated NO production, whereas mutation of serine-1179 to aspartate, mimicking the negative charge afforded by the phosphate, results in constitutive activation of eNOS. More importantly, adenoviral transduction of endothelial cells with activated Akt increased basal NO production, whereas transduction with activation-deficient Akt prevented VEGF-driven NO release. Thus, eNOS is the first plasma membrane-associated substrate of Akt, coupling the release of the potent vasodilator NO to the known vasculoprotective actions of Akt. Two additional groups reported identical results using fluid shear stress and VEGF as ways to activate Akt and eNOS, building a strong consensus that eNOS phosphorylation exerts a

major influence on stimulus-dependent NOS activation (Dimmeler *et al.*, 1999; Michell *et al.*, 1999).

Summary and Model of eNOS Activation/Inactivation

The literature on eNOS subcellular trafficking, studies on protein–protein interactions with caveolin and hsp90, and recent evidence supporting a role of protein phosphorylation have been briefly overviewed. Taking into account the complex interplay of signaling systems, we propose the following working model for eNOS activation in endothelial cells. In cells where eNOS is in caveolae, it is likely that binding to caveolin-1 may negatively regulate its function. On stimulation with calcium-mobilizing agonists such as bradykinin, acetylcholine, or VEGF, the simultaneous recruitment of hsp90 and CaM to eNOS may loosen the eNOS–caveolin inhibitory interaction, thus permitting Akt-induced phosphorylation and NO release. In the context of a stimulus that does not elevate intracellular calcium, such as fluid shear stress (Ayajiki *et al.*, 1996; Kuchan and Frangos, 1994; O'Neill, 1995), estrogen (Caulin-Glaser *et al.*, 1997), and insulin (Tsukahara *et al.*, 1994), the recruitment of hsp90 to eNOS may weaken the eNOS–caveolin interaction. Again phosphorylation by Akt occurs, resulting in NO release. Interestingly, overexpression of dominant negative Akt blocks both VEGF- and shear-induced NO release, suggesting that phosphorylation may be the common denominator for both forms of stimulation. In terms of eNOS inactivation, a decrease in cytoplasmic calcium will facilitate CaM and hsp90 dissociation, and, presumably, eNOS dephosphorylation will re-equilibrate the system back to baseline levels. The temporal and spatial nature of this model is not known. Definitive evidence showing that this mechanism occurs in caveolae is lacking, and such complex interactions may also take place with eNOS localized on the Golgi and in the cytosol. Further dissection of this model utilizing structural biology of protein complexes, reconstituted systems, and dominant negative strategies will permit a clearer picture of eNOS activation to emerge in the not-too-distant future.

NITRIC OXIDE SYNTHASES (NOSS) ARE THE MOST RECENT ADDITION TO A GROUP OF ENZYMES, NOW TOTALING FIVE, THAT RELY ON THE NATURALLY OCCURRING COFACTOR (6*R*)-5,6,7,8-TETRAHYDRO-L-BIOPTERIN (BH₄) FOR CATALYTIC ACTIVITY. INTRACELLULAR LEVELS OF BH₄ DICTATE THE RATE OF NITRIC OXIDE (NO) SYNTHESIS BY NOSS AND EVEN DETERMINE THE END PRODUCT [NO, PEROXYNITRITE (OONO⁻) or (O₂⁻)]. WE NOW APPRECIATE THAT DIVERSE MECHANISMS REGULATE BH₄ EXPRESSION AND, ACCORDINGLY, SERVE AS VERIFIED OR POTENTIAL CONTROL POINTS FOR MODULATING NOS FUNCTION IN PHYSIOLOGY AND PATHOPHYSIOLOGY. INCLUDED IN THE GROUP OF BH₄-DEPENDENT ENZYMES ARE THE THREE AROMATIC AMINO ACID HYDROXYLASES (AAHS; PHENYLALANINE, TYROSINE, AND TRYPTOPHAN HYDROXYLASES), WHERE A REDOX FUNCTION OF BH₄ IN CATALYSIS IS WELL ESTABLISHED AND UNDERSTOOD. DESPITE THE ABSOLUTE DEPENDENCE OF NOS ON BH₄ FOR CATALYTIC FUNCTION, IT IS REMARKABLE THAT PINPOINTING THE MOLECULAR BASIS FOR THIS REQUIREMENT HAS BEEN AN ELUSIVE GOAL. INDEED, THE MECHANISM BY WHICH BH₄ FUNCTIONS IN NO SYNTHESIS IS ARGUABLY THE MOST POORLY UNDERSTOOD ASPECT OF NOS ENZYMOLOGY. THIS GAP IN OUR KNOWLEDGE EXISTS DESPITE RIGOROUS STRUCTURAL AND FUNCTIONAL STUDIES ATTEMPTING TO RESOLVE THE QUESTION OF BH₄ FUNCTION. ONE CERTAIN CONCLUSION IS THAT NOS USES BH₄ IN A MANNER THAT DIFFERS FROM ALL OTHER KNOWN BH₄-DEPENDENT ENZYMES. IN THE FIRST PART OF THIS CHAPTER, WE SURVEY THE ROLES OF PTERINS IN BIOLOGY AND PRESENT OUR CURRENT UNDERSTANDING OF BIOCHEMICAL PATHWAYS THAT DETERMINE BH₄ LEVELS IN MAMMALIAN CELLS AND HOW THEY ARE REGULATED. THIS INCLUDES A DISCUSSION OF GENETIC DEFECTS IN BH₄ METABOLISM. EVIDENCE IS THEN PRESENTED TO SUPPORT THE VIEW THAT BH₄ AVAILABILITY IS A MAJOR DETERMINANT OF MAMMALIAN NO SYNTHESIS RATE IN PHYSIOLOGICAL AND PATHOPHYSIOLOGICAL SETTINGS. FINALLY, WE CONSIDER THE FUNCTION OF BH₄ IN NOS CATALYSIS. ALTHOUGH CONTROVERSIAL, INSIGHTS INTO BH₄ FUNCTION ARE GLEANED BY CONSIDERING THE APPARENTLY UNIQUE ATTRIBUTES OF STRUCTURAL AND FUNCTIONAL INTERACTIONS BETWEEN BH₄ AND NOS ISOFORMS, WHILE JUDICIOUSLY BORROWING FROM OUR KNOWLEDGE BASE OF BH₄ BINDING AND FUNCTION DERIVED FROM STUDIES OF AAHS. THE AUTHORS APOLOGIZE FOR THE SURVEY FORMAT OF THIS VOLUME THAT PRECLUDES SPECIFIC RECOGNITION OF THE MANY IMPORTANT SCIENTIFIC CONTRIBUTORS WHOSE WORK IS SURVEYED HEREIN.

BH₄ Synthesis in Biological Systems

From the Wings of Butterflies to Hydroxylating Cofactor: An Overview of Pteridine Chemistry and Function in Biology

BH₄ is a pteridine, a chemical classification defined by a unique heterocyclic ring structure. The chemical structure of BH₄ is provided in Fig. 1, along with the convention for numbering pterin ring positions. It is notable that biopterin is defined as the pteridine analog wherein the heterocyclic ring is substituted with amino at the 2 position, carbonyl oxygen at the 4 position, and 1,2-dihydroxypropyl at the 6 position. This substituted ring can either be oxidized (biopterin), partially reduced (dihydrobiopterin; BH₂) or fully reduced (BH₄); changes in ring redox status have profound consequences for chemical and biological activity. Asymmetry at C-6 endows biopterin with a stereochemical center; the (6*R*) isomer is naturally occurring. Biopterin devoid of its 6-dihydroxypropyl side chain is termed *pterin*, a heterocycle common to biopterin, folate, and molybdopterin cofactors. We now appreciate that pteridines have a broad range of functions in biology, ranging from eye pigments to light-gathering molecules to enzyme cofactors for redox and one-carbon transfers.

The first studies of what proved to be pteridines in biology can be traced to 1889, when Sir Frederick Gowland Hopkins reported attempts to isolate and purify the yellow pigments from wings of English butterflies (Hopkins, 1889). Elucidation of structures comprising three of these wing pigments was achieved by Robert Purmann in the early 1940s (xanthopterin, leucopterin, and isoxanthopterin), revealing that all share a novel pyrazine [2,3-*D*]pyrimidine ring system that is the defining feature of the pteridine class of compounds. The name *pterin* originates from the Greek word *ptera* for wing, in recognition of the biological source from which members of this chemical class were first identified.

The field of pteridine chemistry advanced significantly in 1957, when Max Viscontini's group reported the isolation of two blue fluorescent eye pigments from *Drosophila melanogaster* (Viscontini and Karrer, 1957); these novel structures

termed HB₁ and HB₂ (for the German *Himmel Blau*, HB) proved to be pterin and biopterin. At a similar time in another field, the protazoan *Crithidia fasciculata* was found to require high levels of folic acid for growth. Biopterin was shown to substitute for folic acid in supporting growth. Further studies lead to the elucidation of a pteridine-dependent reaction unique to *Crithidia* and related microorganisms, involving conversion of dihydroorotic acid to orotic acid. These early studies gave a first glimpse at the cofactor roles that would be revealed for redox cycling pterins.

A seminal report by Seymour Kaufman in the early 1960s (Kaufman, 1963) revealed that 5,6,7,8-tetrahydrobiopterin is the identity of the essential cofactor for metabolism of phenylalanine to tyrosine by phenylalanine hydroxylase in liver. BH₄ was later established as the reducing cofactor for two other mammalian AAHs, namely, tyrosine hydroxylase and tryptophan hydroxylase. Thus, BH₄ was established to play an essential role in biosynthesis of the hormone epinephrine and monoaminergic neurotransmitters: dopamine, norepinephrine, and serotonin. Although it is clear that the mechanistic role of BH₄ in AAH-mediated catalysis is for activation of molecular oxygen, additional regulatory functions of AAHs are subserved by BH₄. For example, BH₄ binding elicits allosteric effects on phenylalanine hydroxylase that modulate the binding of substrate and phosphorylation by A-kinase. Another role for BH₄ is as the hydroxylating cofactor in the oxidative cleavage of acyl glyceryl ethers, catalyzed by the enzyme glyceryl ether monooxygenase.

The observation that high levels of pterin are present in blood, spleen, and lung, tissues that contain negligible levels of AAHs, hinted at additional roles for BH₄. One putative function of BH₄ is in hematopoietic cell proliferation and differentiation. Although the molecular mechanisms and physiological importance remain uncertain, it is intriguing that BH₄ appears specifically during the differentiation of reticulocytes to erythrocytes and undergoes cell cycle-dependent expression in diverse species. Notably, in both mammalian thymocytes and the acellular slime mold *Physarum*, BH₄ levels are observed to peak during the S phase (Zhuo *et al.*, 1996; Werner-Felmeyer *et al.*, 1994). A role for BH₄ in the cell cycle is further suggested from studies in *Drosophila* that demonstrate mitotic asynchrony, persisting chromatin bridges, and death of embryos treated with an inhibitor of BH₄ synthesis or possessing a mutation that incapacitates *de novo* BH₄ synthesis (Chen *et al.*, 1994).

An aspect of BH₄ function that remained mysterious for many years was a dramatic and well-documented induction of BH₄ synthesis in mammalian cells by cytokines, in the absence of a known enzyme that was both cytokine inducible and BH₄ dependent. A role for immunostimulant-evoked BH₄ synthesis was clarified with the key discovery that extracts of cytokine-activated macrophages produce NO from L-arginine in a BH₄-dependent manner (Kwon *et al.*, 1989; Tayeh and Marletta, 1989). Although it had been considered that this BH₄-dependence might be a unique feature of cytokine-activated NO synthesis, inasmuch as NO synthesis

(6*R*) 5,6,7,8-tetrahydro-L-biopterin

Figure 1 Structure of BH₄, the naturally occurring pterin cofactor of NOSs and AAHs. The standard nomenclature for numbering the positions of the pteridine ring and the biopterin side chain is indicated.

by brain extracts was not similarly increased after addition of excess BH₄, the suggested isoform dissimilarity proved incorrect. Indeed, the demonstration of a BH₄ dependence from nNOS was hindered by the high affinity it possesses for BH₄ binding, causing nNOS to be BH₄ replete as isolated. We now know that each of the three mammalian NOS gene products require BH₄ for activity, as do NOS homologs from each of the diverse species yet examined. The universal requirement of NOSs for BH₄ is not surprising; indeed, given the intricacies of NOS enzymology, it is unlikely that nature would ever invent the chemistry twice! Inasmuch as NOS performs two successive monooxygenation reactions on the substrate arginine, once it was revealed that BH₄ functions as NOS cofactor, it became obvious that one or both NOS reactions would be catalyzed by a mechanism analogous to

that for AAHs, wherein BH₄ serves to activate molecular oxygen. Remarkably, NOSs have failed to live up this prophesy. Although a redox function for BH₄ in NOS catalysis remains possible, if not likely, pterin mechanisms and intermediates are assuredly unique. The role of BH₄ in NOS catalysis is addressed later.

De Novo Synthesis of Tetrahydrobiopterin: General Features of the Pathway

BH₄ is synthesized from guanosine 5'-triphosphate (GTP) in four enzymatic steps, requiring three distinct enzymes (see Fig. 2). The first and rate-limiting reaction is catalyzed by GTP cyclohydrolase I (GTPCH; EC 3.5.4.16), an enzyme that converts GTP to 7,8-dihydroneopterin triphosphate

Figure 2 The *de novo* tetrahydrobiopterin synthetic pathway.

(NTP). In this complex but pivotal step, GTPCH acts in a concerted reaction to open the imidazole ring of GTP, releasing C-8 as formate, triggering an Amadori rearrangement of the ribose ring carbons, and creating a cyclic six-membered pyrazine ring. GTPCH-catalyzed formation of NTP is a common initial step in the biosynthesis of unconjugated pterins, folates, and riboflavin, but not molybdopterin (a cofactor of sulfite oxidase, xanthine dehydrogenase, and aldehyde oxidase in humans). GTPCH (actually GTPCH I) should not be confused with the unrelated enzyme GTP cyclohydrolase II that catalyzes the second step in riboflavin biosynthesis by microorganisms. As discussed later, GTPCH provides the major target for pathway regulation; GTPCH activity is regulated by diverse mechanisms, including transcriptional, translational, and posttranslational levels. A recently elucidated physiological mechanism for posttranslation control of GTPCH activity involves feedback inhibition by BH₄ and other pterin analogs. Notably, feedback inhibition results from BH₄-induced complex formation of GTPCH with a regulatory protein known as GTPCH feedback regulatory protein, a species whose sequence was first inferred from cDNA cloning in 1997 (Milstien *et al.*, 1996). A prototypic inhibitor of GTPCH activity is 2,4-diamino-6-hydroxypyrimidine (DAHP); this agent mediates GTPCH inhibition both by triggering BH₄-like feedback inhibition and by competing for the binding of substrate GTP (Xie *et al.*, 1998).

In the second step of BH₄ synthesis, 6-pyruvoyltetrahydropterin synthase (PTPS; EC 4.6.1.10) catalyzes the conversion of NTP to 6-pyruvoyltetrahydropterin. The PTPS reaction is magnesium and zinc dependent, involving intermolecular redox rearrangement of N-5, C-6, and C-1 of NTP, followed by nonenzymatic triphosphate elimination from the three-carbon side chain on C-6. Although GTPCH is rate limiting to BH₄ synthesis in most cells and circumstances, PTPS has been suggested to limit BH₄ synthesis specifically in human hepatocytes, and PTPS may become the rate-limiting enzyme in other cell types after exposure to immunological stimuli that trigger upregulation of GTPCH activity (discussed below). Although it has been reported that PTPS requires phosphorylation to be fully active, this posttranslational modification has not been affirmed as a site for regulation of enzyme activity *in vivo*. No inhibitor of PTPS has yet been described.

The final step in the *de novo* synthesis involves two successive NADPH-dependent reductions of the C-1' and C-2' oxo groups of 6-pyruvoyltetrahydropterin to form BH₄; both reactions are catalyzed by the enzyme sepiapterin reductase (SR, EC 1.1.1.153). SR catalysis involves proton transfer to the C-1' and C-2' carbonyl groups, accompanied by a stereospecific side-chain isomerization. The C-1' position appears to be the predominant initial site of reduction, resulting in formation of the unstable intermediate 1-hydroxy-2'-oxopropyltetrahydropterin. Inasmuch as SR activity is abundant in all BH₄-producing cells studied to date, it does not appear to be a generic site for regulation of BH₄ synthesis. Nonetheless, SR is potently inhibited by the serotonin metabolite *N*-acetylserotonin, presenting the possibility for a

highly specific feedback regulatory mechanism between indole amines and pterins *in vivo*. *N*-Acetylserotonin (NAS) and *N*-acetyldopamine are potent and selective inhibitors of SR that have been used to assess the role of SR in biological systems (Smith *et al.*, 1992).

Regeneration of Tetrahydrobiopterin for Sustained AAH Activity

Although BH₄ may be redox active in catalysis by NOS isoforms, a dihydropterin product is certainly not released as a stoichiometric product with NO. Indeed, if an oxidized derivative is produced from BH₄ in the course of NOS catalysis, this intermediate is most certainly regenerated to BH₄ *in situ*, while bound to NOS. In contrast, for aromatic amino acid hydroxylases (AAHs) BH₄ is oxidized and then released as the unstable species 4a-hydroxytetrahydrobiopterin¹ (pterin-4a-carbinolamine), leading to potential accumulation of the dehydration product, 5,6-dihydrobiopterin (also known as quinonoid dihydrobiopterin or q-BH₂). If q-BH₂ accumulated without its regeneration to BH₄, the function of BH₄ in aromatic amino acid hydroxylation would be as a stoichiometric substrate, rather than the catalytic cofactor that it is. Thus, a two-enzyme pathway exists for efficient recycling of q-BH₂ to BH₄, thereby enabling BH₄ to function as a catalytic cofactor of AAHs. This pterin cycling pathway is depicted in Fig. 3.

The oxidant required for aromatic amino acid hydroxylation is an unstable pterin species in which dioxygen is transferred from nonheme iron, in the active site of AAHs, to the C-4a position of the bound BH₄ cofactor. From the resulting 4a-hydroperoxytetrahydrobiopterin, one atom of oxygen is inserted into an aromatic amino acid substrate, and a second oxygen atom is retained as the hydroxyl group in the pterin product, pterin-4a-carbinolamine. Pterin-4a-carbinolamine is subsequently dehydrated to q-BH₂. Although the dehydration to q-BH₂ does occur efficiently nonenzymatically, dehydration is markedly accelerated by the enzyme 4a-hydroxytetrahydropterin dehydratase (PCD). PCD was first identified as a contaminant in a purified phenylalanine hydroxylase preparation that enhanced BH₄-stimulated hydroxylating activity (Kaufman, 1970). The critical importance of PCD to BH₄-mediated catalytic function is implicit in the identification of patients with BH₄ deficiency (manifest as atypical phenylketonuria) arising from mutation of the gene encoding PCD. The major function of PCD may be to prevent the accumulation of 7-BH₄, an AAH inhibitory species that arises during nonenzymatic dehydration of pterin-4a-carbinolamine that is formed as a result of dihydroxypropyl side-chain migration from the 6 position to the 7 position of the pterin ring. Knowledge of the amino acid sequence of

¹ Although this is a tetrahydropterin, considering the number of double bonds in the system, the term quinonoid dihydrobiopterin c4a-hydrate provides a better appreciation of redox state and chemical properties. In any event, a commonly used alternative name is pterin-4a-carbinolamine, which does not comment on the issue of ring redox state.

Figure 3 Pathways for salvage and recycling of BH₄. Abbreviations: 7,8-BH₂, 7,8-dihydrobiopterin; SR, sepiapterin reductase; DHFR, dihydrofolate reductase; PH, phenylalanine hydroxylase; TH, tyrosine hydroxylase; TrH, tryptophan hydroxylase; PCD, pterin-4a-carbinolamine dehydratase; DHPR, dihydropteridine reductase.

PCD revealed it to be a protein with a remarkable dual function—PCD is identical to a previously identified transcription factor, identified in mammalian cell nuclei, that regulates dimerization of a homeodomain protein (Citron *et al.*, 1992). In this other identity, PCD was known as *dimerization cofactor of hepatocyte nuclear factor 1α* (DCoH). The two activities of PCD/DCoH are thought to be completely unrelated, explained by coevolution of independent protein functions.

The final step in BH₄ recycling from q-BH₂ is mediated by the NADH- or NADPH-dependent enzyme dihydropteridine

reductase (DHPR). DHPR is a ubiquitous enzyme that functions to reduce q-BH₂ and not 7,8-dihydropterins.

The Pterin Salvage Pathway

Independent of the BH₄ regeneration pathway described above, a pathway exists to recycle BH₄ after nonenzymatic ring oxidation to its dihydropterin counterpart. Thus, 7,8-dihydrobiopterin (BH₂) is produced nonenzymatically, when BH₄ is exposed to an oxidative environment, and can be salvaged as BH₄, at the expense of NADPH (see Fig. 3). The

enzyme that catalyzes this reaction is dihydrofolate reductase (DHFR), well known for its role in regenerating reduced 5,6,7,8-tetrahydrofolates from 7,8-dihydrofolates. Notably, DHFR does not reduce $q\text{-BH}_2$, and thus does not have DHPR activity. Methotrexate (MTX) and related cytotoxic drugs are potent and selective inhibitors of DHFR, although these agents also inhibit DHPR, albeit at higher drug concentrations. Thus, clinical use of MTX effectively blocks the regeneration of tetrahydrofolates and tetrahydropterins. Although it is assumed that the clinical efficacy of MTX in chronic inflammatory conditions (e.g., rheumatoid arthritis) is a consequence of reduced tetrahydrofolate depletion, a therapeutic effect arising from BH_4 depletion cannot be discounted. Indeed, NO production and toxicity have been demonstrated in joints of arthritic patients, and BH_4 depletion can limit the production of cytotoxic quantities of NO (or NO-derived species). Further work is needed to define the extent to which anti-inflammatory effects of DHFR inhibitors arise specifically through BH_4 depletion. As indicated in Fig. 3, SR extends the BH_4 salvage pathway by catalyzing the reduction of sepiapterin to 7,8- BH_2 ; this activity is distinct from the role of SR in the *de novo* synthesis of BH_4 from GTP. Intracellular pools of sepiapterin can arise by oxidation of tetrahydropterin intermediates from the *de novo* BH_4 pathway (e.g., 6-lactoyltetrahydropterin).

Plasma Neopterin as a Marker for BH_4 Synthesis in Humans

The concentration of neopterin in human plasma is a convenient indicator of *de novo* BH_4 synthesis. Neopterin arises as a metabolite of GTPCH-produced NTP. When GTPCH becomes markedly activated in human cells, NTP accumulates due to a relative insufficiency of the subsequent enzyme, PTPS. Intracellular NTP is then subject to the action of phosphatase, which is released from cells into the circulation, and it is nonenzymatically oxidized from dihydro-neopterin to yield plasma neopterin. Compared with humans, rodents possess significantly greater levels of PTPS, explaining the relative lack of neopterin in murine cells, tissues, and body fluids (Werner *et al.*, 1991).

Before any clear function could be ascribed, plasma neopterin levels had been recognized as a sensitive indicator of immune cell activation for clinical diagnosis (Wachter *et al.*, 1989). Since the only presently known function of immunologically evoked BH_4 synthesis is to support coinduced NO synthesis, elevated neopterin levels presumably signal inducible NOS (iNOS) activation. In this regard, it is notable that neopterin concentrations correlate with the extent and the activity of disorders in which cell-mediated immune stimulation play a role. In allograft recipients, neopterin concentrations rise early during the course of rejection episodes. Increasing neopterin is among the first signs of infection by virus. In inflammatory conditions such as rheumatoid arthritis, neopterin levels correlate with the extent and activity of the disease. Neopterin also has long been known to be a potent marker for HIV progression. It is tempting to consider

that neopterin informs us of iNOS induction in each of these clinical circumstances.

Genetic Diseases Arising from BH_4 Deficiency

Although rare, numerous inborn errors of BH_4 metabolism have been documented in human patients. Given that knockout of a single BH_4 -dependent enzyme (tyrosine hydroxylase) is embryonic lethal in mice, inactivating all BH_4 -dependent enzymes should similarly be incompatible with life. Accordingly, observed patient mutations are likely to arise from severe, but incomplete, deficiencies in BH_4 expression. Failure to identify specific symptoms that derive from NOS deficit in these patients may reflect in part the overall severity of phenotype; additionally, a much lower level of BH_4 is required to support activity of NOSs, compared with AAHs ($\sim 1/1000$). Thus, a deficiency in AAH activity is predicted to manifest with BH_4 levels that are fully sufficient for maximal NOS activity. An international database of mutations causing BH_4 deficiency, along with predicted amino acid sequences of the cognate proteins, is available (www.ivr.unizh.ch/blau/biodef1.html).

ATYPICAL PHENYLKETONURIA

BH_4 deficiency gives rise to a variant of hyperphenylalaninemia, termed atypical phenylketonuria. This condition presents phenotypically with hyperphenylalaninemia associated with depletion of the neurotransmitters dopamine and serotonin. Atypical phenylketonuria has been found to arise from mutations in any of four genes. These include genes encoding for two of three enzymes required for *de novo* BH_4 synthesis (GTPCH and PTPS) and each of the two enzymes required for BH_4 regeneration from pterin-4a-carbinolamine (PCD and DHPR). Inherited deficiencies of GTPCH and PTPS are clinically characterized by severe neurological symptoms unresponsive to the classic low-phenylalanine diet. Out of several hundred patients registered in the international data base, 57% suffer from PTPS deficiency and 4% from GTPCH deficiency. The failure to identify SR mutations that manifest as a atypical phenylketonuria suggests that one or more other enzymes may be capable of substituting for SR in catalyzing the final reductive step in *de novo* BH_4 synthesis.

PARKINSONISM AND DOPA-RESPONSIVE DYSTONIA

Catecholamine biosynthesis is regulated by tyrosine hydroxylase (TH) and available BH_4 cofactor. Total biopterin (essentially all BH_4) is highly concentrated in the striatum and specifically enriched in nigrostriatal dopaminergic nerve terminals. Throughout the human brain, there is a positive correlation between total biopterin content and TH activity. In patients with classical Parkinsonism, typified by degeneration of nigrostriatal dopaminergic neurons, neuronal cell death is associated with decreased biopterin levels in cerebrospinal fluid (CSF). The extent of biopterin lowering in CSF may reflect the degree of dopaminergic neuron loss in these patients.

Genetic deficiency in GTPCH activity, inherited in an autosomal dominant pattern, was shown to correlate with dopamine depletion and progressive development of dystonia (Ichinose *et al.*, 1994). Dystonia was characterized by marked diurnal fluctuations in dopamine metabolites, with an increased incidence in females. Patients responded to relatively low doses of L-3,4-dihydroxyphenylalanine (DOPA); thus, this form of GTPCH deficiency was termed DOPA-responsive dystonia (DRD). When GTPCH activity is decreased to less than 20% of normal, activity of TH in the nigrostriatal dopaminergic neurons declines to a level that apparently triggers symptoms of DRD. The candidate gene for DRD was mapped to chromosome 14q by linkage analysis. Subsequently, the first mutations in the GTPCH gene were identified (Ichinose *et al.*, 1995), confirming that it must be a gene for DRD. In contrast to DRD, juvenile Parkinsonism patients have normal GTPCH activity. In Parkinson's disease, GTPCH, TH, and dopamine in the striatum decrease in parallel, secondary to death of dopaminergic neurons. Autosomal dominance of GTPCH mutations may be understood from the obligate decameric structure of GTPCH. Inasmuch as each GTPCH active site is formed at the interface of three subunits (see later for structural details), a single functionally inactive GTPCH gene product would predictably result in 87.5% of enzyme active sites containing at least one mutant subunit. This would predict autosomal dominance of the trait (further assuming that decameric assembly of mutant subunits is not impaired and each of the parental GTPCH gene products are equivalently expressed). On the other hand, if the mutant GTPCH subunit were incapable of decamerization, but expressed at levels equal to the wild type, all GTPCH decamers would have full activity, but the enzyme concentration would be diminished by 50%—such a scenario would anticipate a recessive pattern of inheritance.

VITILIGO AND PIGMENTATION DISORDERS

The importance of BH₄ in the human epidermis is well recognized. Both epidermal melanocytes and keratinocytes have a basal capacity for *de novo* synthesis and recycling of BH₄, thereby enabling PAH activity. While both cell types need PAH to produce tyrosine, the fate of tyrosine is markedly different in each case. Notably, keratinocytes use tyrosine as a precursor of catecholamine biosynthesis via TH, whereas melanocytes use tyrosine for melanin biosynthesis, via the action of tyrosinase. In accord with the finding that tyrosinase mRNA levels are identical in white and black skin, enzyme activity is thought to be regulated by substrate supply or another mode of moment-to-moment regulation. Patients with the skin depigmentation disorder vitiligo suffer from dysregulation in melanin biosynthesis. In vitiligo, the ability of PDC in skin to dehydrate pterin-4a-carbinaolamine was shown to be low or absent, resulting in a reduced rate of BH₄ regeneration and accumulation in epidermis of the non-enzymatic dehydration product, 7-BH₄. Importantly, 7-BH₄ is a potent competitive inhibitor of the PAH reaction. Thus, 6-BH₄ seems to control melanin biosynthesis in the human

epidermis, whereas 7-BH₄ may initiate depigmentation in patients with vitiligo. It is notable that 6-BH₄ and 7-BH₄ also specifically bind and inhibit tyrosinase activity; this binding and inhibition are reversed by UVB light. Thus, BH₄s may serve as a photoswitch to regulate *de novo* melanogenesis. Tyrosinase complexes formed with 7-BH₄ are significantly less photolabile than those with 6-BH₄, offering another mechanism by which 7-BH₄ attenuates melanin biosynthesis.

A MOUSE MODEL OF BH₄ DEFICIENCY

The *hph-1* mouse was created by chemical mutagenesis of spermatogonial stem cells and by a breeding scheme that selects for recessive mutations giving rise to hyperphenylalaninemia (McDonald and Bode, 1988). Analysis of the *hph-1* mouse phenotype revealed a BH₄ deficiency, arising from mutation in the GTPCH gene. The mutation does not alter the sequence within the reading frame of GTPCH but apparently diminishes steady-state levels of GTPCH mRNA. It is therefore presumed that the defect resides in the regulatory region of the GTPCH gene. The mutation leads to greatly reduced levels of BH₄ in liver and brain, hyperphenylalaninemia, and impaired monoamine transmitter synthesis. Since DRD results from mutations in the gene for GTPCH, the mouse model may be useful to assess the pathophysiology of DRD and investigate novel therapeutic approaches. Indeed, *hph-1* mice and patients with DRD are very similar, neurochemically. Although standard therapy for DRD involves monoamine replacement therapy, this approach should not alleviate a deficit in NOS activity. Thus, it is significant that the *hph-1* mouse has an apparent impairment of brain NOS activity, indicated by low levels of cGMP, and this deficit can be corrected with peripherally administered BH₄. This observation suggests that patients with DRD may have a previously unrecognized NOS deficiency, owing to diminished availability of BH₄ cofactor in brain. Accordingly, consideration should be given to the development and use of agents that can reactivate NOS in DRD patients.

Regulation of BH₄ Synthesis in Mammalian Cells

GTPCH Structure and Localization: An Overview

GTPCH is a homodecamer of 27- to 29-kDa subunits that is remarkably conserved throughout the phylogenetic kingdom; *Escherichia coli* and rat enzymes are 73% identical. High-resolution crystal structures of the *E. coli* GTPCH reveals two face-to-face pentameric torroids of 100 Å diameter and 65 Å in depth. Ten substrate binding pockets are created around the outer torroid circumference, each 10 Å deep, formed by surfaces of three adjacent subunits (Nar *et al.*, 1995). Although a high-resolution structure is not yet available for a mammalian GTPCH, the rat homolog was confirmed to resemble the *E. coli* enzyme in having a homodecameric structure (Steinmetz *et al.*, 1998). Given that an active site is formed at the interface of three subunits,

contributed by face-to-face pentamers, it is anticipated that the decameric structure of GTPCH will prove to be obligate for function. A distinct feature of mammalian GTPCH subunits is the presence of an EF-hand motif that binds Ca^{2+} with high affinity. The functional significance of Ca^{2+} binding by GTPCH is unknown; however, it is notable that GTPCH activity has recently been reported to increase with calcium influx into cells (Hwang *et al.*, 1999).

The structural homology of GTPCH with PTPS and two related enzymes (dihydroneopterin aldolase and dihydro-neopterin epimerase) reveals an evolutionarily conserved protein fold common to pterin biosynthetic enzymes. Although the only GTPCH structure yet solved is from *E. coli*, homology-based three-dimensional computer modeling suggests the rat homolog is extremely similar (S. Gross, unpublished finding). Indeed, the degree of sequence homology and goodness of fit ensure the overall accuracy of this model. The only indeterminate region of significant length is the N-terminal 54 amino acids of rat GTPCH; this sequence is unique to mammalian GTPCHs and could not be fit, as there is no structural homolog in bacterial GTPCHs. It is notable that the N-terminal sequence of GTPCH is conserved among mammalian species and is not required for catalysis; thus, it is anticipated to serve regulatory functions unique to mammals.

In situ hybridization and immunohistochemical staining reveal that GTPCH is predominantly localized to the adrenal medulla and tyrosine hydroxylase-expressing cells of the substantia nigra, ventral tegmental area, hypothalamus, and locus ceruleus (Hwang *et al.*, 1998; Nagatsu *et al.*, 1995). Among tryptophan hydroxylase-containing cells, GTPCH is particularly abundant in the dorsal raphe nucleus and pineal gland. Neither GTPCH mRNA nor protein expression is pronounced in neurons or endothelial cells that constitutively express NOS isoforms; this may be explained by the low levels of low levels of BH_4 utilized by NOSs compared with AAHs. Alternatively, it is conceivable that BH_4 is produced in AAH-containing neurons and delivered to NOS-containing neurons (presumably as 7,8- BH_2).

Staining and electron microscopy indicate that GTPCH protein in neurons resides in cytosol and also in association with microtubules in axonal processes (Nagatsu *et al.*, 1995). GTPCH expression is induced by immunostimulants in many cell types in which iNOS is coinduced (see below). Although cytokine-induced GTPCH is largely cytosolic, a distinct membrane-associated component is observed with unknown function (Xie *et al.*, 1998).

Induction of GTPCH Activity

The first evidence of GTPCH induction was provided in 1981, when it was shown that administration of either reserpine or insulin to rats elicits an increase in adrenal medullary GTPCH activity (Viveros *et al.*, 1981). A requirement for *de novo* protein synthesis in GTPCH induction was implied by the finding that these effects were attenuated by coadministration of cycloheximide. Subsequently, GTPCH mRNA levels were also shown to increase in the adrenal medulla

following cortisol treatment, suggesting but not proving steroid-induced transcriptional upregulation of the GTPCH gene. This mode of GTPCH regulation may be physiologically relevant to the regulation of epinephrine biosynthesis but apparently not to that of NO.

Several years later it was shown that GTPCH activity was also induced by immunostimulants (for review, see Werner *et al.*, 1998). Thus, *in vitro* studies of human peripheral blood mononuclear cells revealed that γ -interferon (IFN- γ) stimulated production of the GTPCH-derived product, neopterin. This finding established a connection between GTPCH activation and the elevated neopterin levels observed in plasma patients with viral infections and tumors. Inasmuch as a function for immunologically evoked BH_4 synthesis was unknown, the finding of cytokine-induced GTPCH activity was initially perplexing. We now appreciate that the pivotal function of immunostimulant-induced GTPCH is to provide the BH_4 cofactor needed for support of coinduced iNOS. Interestingly, coinduction of GTPCH and NOS is a phenomenon that is not restricted to mammals; it also occurs in other eukaryotes such as the slime mold *Physarum polycephalum* (Werner-Felmeyer *et al.*, 1994).

GTPCH induction by immunostimulants and mitogens has been observed in most cells and tissues studied, although specific activating signals vary with cell type. Stimuli that induce GTPCH in a given tissue have generally been observed either to enhance the activity of basally expressed NOS isoforms or to be essential for the activity of coinduced iNOS protein, or both. Various cell types have been used to study the mechanistic basis for GTPCH induction.

In mononuclear cells and macrophages, GTPCH activity is induced by stimuli such as IFN- α , - β , - γ , interleukin 2 (IL-2), kit-ligand, bacterial endotoxins such as lipopolysaccharide (LPS), phytohemagglutinin, and pokeweed mitogen. The effects of these stimuli tend to be synergistic with one another. Many of these agents have also been found to induce GTPCH expression in numerous other cell types, including thymocytes, dermal fibroblasts, mast cells, vascular smooth muscle cells and endothelial cells, and glomerular mesangial cells. The ubiquitous induction of GTPCH is not a cell culture artifact and has been observed *in vivo*. For example, LPS administration to rats elicits a substantial increase in GTPCH activity in muscle, lung, heart, kidney, and aorta (Hattori *et al.*, 1996; Hussain *et al.*, 1997).

Induction of GTPH activity by immunostimulants and mitogens has been associated with significant increases in the expression of GTPCH mRNA, and it is presumed to occur as a result of transcriptional upregulation of the GTPCH gene; nonetheless, definitive proof is lacking from the literature. In preliminary studies of reporter gene constructs, stably transfected into rat aortic smooth muscle cells, we have found that the initial 1 kb of 5'-upstream DNA sequence to the rat GTPCH gene confers threefold inducibility by LPS (S. S. Gross and C. L. Jones, unpublished finding). It is unclear whether this level of transcriptional upregulation is sufficient to explain the more substantial (>30-fold) induction of GTPCH mRNA and activity observed in these cells with LPS. Additional DNA sequence

may mediate more profound transcriptional upregulation by LPS, although 1 kb and 6 kb of 5'-upstream GTPCH gene fragments gave indistinguishable results. Given that LPS-induced transcription of the iNOS gene has been linked to an NF- κ B response element that resides within 80 bp of the transcription start site, it is notable that the rat GTPCH gene also displays an NF- κ B consensus element immediately upstream of transcription start. Function of the NF- κ B element in mediating LPS-induced GTPCH expression has not been established but is suggested from the finding that GTPCH induction is blocked by the NF- κ B inhibitor pyrrolidine dithiocarbamate (Hattori *et al.*, 1996).

Cytokines, growth factors, and immunosuppressants have been identified that attenuate GTPCH activity or its induction. For example, in cultured human endothelial cells IL-4, IL-10, and transforming growth factor β (TGF- β) deactivate GTPCH. In rat smooth muscle cells TGF- β , thrombin, ciliary neurotrophic factor, and leukemia inhibitory factor downregulate LPS-induced GTPCH expression. In macrophages, endothelial cells, cardiac myocytes, and some other cell types, cyclosporin, FK506, and glucocorticoids elicit GTPCH downregulation. Although these latter agents downregulate immunostimulant-induced NO synthesis, this effect is not exclusively mediated by BH₄ depletion, an iNOS induction is also attenuated. Upregulation of GTPCH has been observed with NGF and EGF in neuronal-like cell lines; given that these cells express both NOS and AAHs, the function of resulting BH₄ may conceivably be to support both catecholamine and NO biosynthesis.

Cyclic AMP may also be an important regulator of GTPCH. Cell-permeant analogs of cAMP and the adenylate cyclase activator forskolin have been found to either increase GTPCH expression directly in some cell types (mesangial cells, vascular smooth muscle cells, adrenal chromaffin cells, neuronal cells, and neuronal-like cell lines) or potentiate GTPCH induction by IL-1 β and other immunostimulants (most cell types). Increases in cAMP apparently mediate GTPCH induction via the action of several hormones in tissues containing cognate receptors that trigger A-cyclase activation; these hormones include vasopressin, adrenomedullin, and adrenocorticotrophin. Although a putative cAMP response element binding protein (CREB) consensus element is identified within the rat GTPCH promoter, the function has not been verified.

Posttranslational Regulation of GTPCH

Phosphorylation of GTPCH has been reported to occur in PC12 cells after KCl-induced depolarization. Although neither the precise site nor the functional consequences of this phosphorylation on enzyme activity have been evaluated, it was shown to be coincident with a protein-protein interaction between GTPCH and the monomeric G protein rabphilin 3A (Rab3A). It is yet unclear whether the reported GTPCH-Rab3A interaction is direct or involves additional protein components. Since Rab3A is a component of synaptic vesicle membranes, playing a role in vesicle translocation and transmitter release, it is conceivable that subcellular lo-

calization of GTPCH is modulated by phosphorylation, perhaps controlling intracellular compartmentalization of BH₄ synthesis.

Phorbol esters that activate protein kinase C (PKC) have been reported to increase the neopterin and biopterin content in T lymphocytes in culture. In cultured dopaminergic neurons, adenylate cyclase activation and membrane depolarization affect GTPCH expression and increase BH₄ biosynthesis. Similarly, reagents that increase intracellular levels of cAMP have been shown to cause an elevation of GTPCH activity in some experimental settings. Such evidence suggests that in addition to induction of GTPCH, post-translational modifications such as phosphorylation may play a role in GTPCH regulation. Indeed, GTPCH appears to be basally phosphorylated in mast cells, and both phosphorylation and activity transiently increase on IgE receptor activation (Hesslinger *et al.*, 1998). Although phosphorylation of GTPCH has been demonstrated *in vitro* with casein kinase II and PKC, the regulatory significance of these modifications *in vivo* are unknown.

Feedback Inhibition of GTPCH by BH₄/GFRP

It was appreciated for many years that GTPCH is inhibited by BH₄; thus *de novo* BH₄ synthesis is regulated by end product inhibition. The capacity to inhibit GTPCH is not restricted to BH₄; it is observed with many pterins, most potently with reduced pterins (Ballahsene *et al.*, 1984; Shen *et al.*, 1988). It was a surprise when studies of rat GTPCH, purified from a bacterial expression system, revealed no inhibition of activity by BH₄ *in vitro*. This led to the identification of a novel protein in liver that bound to purified recombinant GTPCH in the presence of BH₄ and reconstituted the ability of BH₄ to inhibit purified recombinant GTPCH (Harada *et al.*, 1993). Initially named p35 based on an apparent molecular mass of 35 kDa, this protein was cloned and found to encode an 84-amino-acid polypeptide, comprising only 9.5 kDa (Milstien *et al.*, 1996). p35 was renamed GFRP, for GTPCH feedback regulatory protein. In the presence of bacterially expressed rat GFRP, BH₄ was found to elicit a concentration-dependent and complete inhibition of recombinant GTPCH. This finding affirmed that the 9.5-kDa GFRP was both necessary and sufficient for BH₄-mediated feedback inhibition of GTPCH. GFRP appears to be a homopentamer, and it is speculated that one GFRP pentamer interacts with each of the two pentameric faces of GTPCH decamer (Yoneyama and Hatakeyama, 1998). GFRP-mediated inhibition of GTPCH is specifically reversed by phenylalanine, explaining the clinical observation that a Phe-rich meal increases circulating levels of total biopterin. Although phenylalanine reverses inhibition of GTPCH imposed by GFRP/BH₄, it does not dissociate the protein assembly. A model that summarizes this mechanism for feedback inhibition of GTPCH by pterins is depicted in Fig. 4.

Given that the K_m of BH₄ for support of NOS activity is extremely low (30–100 nM) in comparison with that reported for feedback inhibition (1–10 μ M), it was not

Figure 4 Schematic to depict the role of GFRP as a mediator of GTPCH feedback inhibition by BH_4 . When either BH_4 or phenylalanine are present in sufficiently high concentration, one GFRP pentamer is bound to each free GTPCH decamer. Whereas phenylalanine-bound GFRP promotes GTPCH activity, BH_4 binding inhibits GTPCH activity. See color insert.

anticipated that feedback inhibition of GTPCH could influence NOS activity. Nonetheless, GFRP mRNA is detectable in vascular smooth muscle cells and inducible by immunostimulants, and GFRP mediates tonic inhibition of GTPCH (in the absence of Phe) when BH_4 synthesis is induced by immunostimulants (Xie *et al.*, 1998). Whether this system significantly impacts on immunostimulant-induced NOS activity *in vivo* remains to be ascertained.

Other Sites for Regulation of BH_4 Synthesis

PTPS

6-Pyruvoyltetrahydropterin synthase (PTPs), the enzyme catalyzing the second step in BH_4 biosynthesis, has been purified from human liver and rat brain. PTPS has homology to aldose reductase, which catalyzes the reduction of a wide variety of carbonyl compounds to their corresponding alcohols in an NADPH-dependent reaction. Based on knowledge of the broad range of catalytic efficiencies for aldose reductase, it is conceivable that PTPS might also function as a reductase, especially in circumstances where SR is rate limiting or genetically impaired.

In humans, levels of PTPS become rate limiting after GTPCH upregulation. Full activity of PTPS depends on phosphorylation by cGMP-dependent kinase (Ser-19 in human PTPS; Scherer-Opplinger *et al.*, 1999). Since NO activates soluble guanylate cyclase, triggering increases in cGMP and cGMP-dependent kinase activity, PTPS activa-

tion should occur as a consequence. Phosphoregulation of PTPS and upregulation of BH_4 production potentially endow NO with the capacity to enhance its own synthesis.

In some cell types, PTPS has been demonstrated to be cytokine-inducible, as is almost uniformly observed for GTPCH. For example, PTPS mRNA and protein activity in human umbilical vein endothelial cells are significantly induced (10-fold and threefold, respectively) by the combination of tumor necrosis factor alpha ($\text{TNF-}\alpha$) and $\text{IFN-}\gamma$, although the extent of this induction is an order of magnitude less than that for GTPCH (Linscheid *et al.*, 1998).

GTP AVAILABILITY

Intracellular GTP levels in hepatocytes and other cells are reported to be in the range of 100–200 μM , approximately the K_m for utilization by GTPCH. Moreover, GTP elicits positive cooperativity in a concentration-dependent manner for increasing the GTPCH reaction velocity. Since GTPCH activity is rate limiting in *de novo* BH_4 synthesis, these findings imply that an increase in availability of GTP substrate would enhance the rate of intracellular BH_4 accumulation. Thus, it is notable that GTP levels in cytokine-activated cells have been found to significantly increase in many cell types, concurrently with GTPCH activity. The mechanism of GTP upregulation by cytokines is not known.

Inosine monophosphate (IMP) dehydrogenase is the rate-limiting enzyme for *de novo* GTP biosynthesis and can be specifically inhibited by mycophenolic acid and 2-amino-

1,3,4-thiadiazole. When these GTP synthesis inhibitors were applied to neuronal-like cell lines that produce catecholamines, BH₄ production was inhibited. Addition of guanine or guanosine (which is converted to GTP by hypoxanthine guanine phosphoribosyltransferase through the purine salvage pathway) restored BH₄ levels and reversed the effects on IMP dehydrogenase inhibition. Inhibition of *de novo* purine synthesis was also found to inhibit NO production in cytokine-activated vascular cells, specifically by preventing the otherwise observed increase in levels of GTP and BH₄.

Biopterin Uptake by Cells

Despite the finding that immunostimulant-activated vascular smooth muscle cells *in vitro* produce BH₄ in quantities which support a rate of NO synthesis that is less than half-maximal (Gross and Levi, 1992), these cells secrete more than 95% of the BH₄ that they produce. Similarly, endothelial cells in culture have been shown to secrete large quantities of BH₄ (Walter *et al.*, 1994). Thus, in cell culture, BH₄ efflux dominates over cell retention. Cell efflux and uptake of BH₂/BH₄ were also indicated by the finding that iNOS-transfected cells produce barely detectable levels of NO when cultured alone, but substantial amounts of NO when cocultured with BH₄-producing cells (Tzeng *et al.*, 1996). Thus, BH₄ may engage in a transcellular metabolism, wherein BH₄ efflux from producing cells provides BH₂ as substrate for uptake and reduction by pterin synthesis-deficient cells. The relatively low amounts of BH₄ needed to support NOSs makes such a cycle feasible for NOS-containing cells, whereas it is unlikely that sufficient BH₄ can be provided to influence AAH activities. Anatomic evidence consistent with intercellular BH₄ transfer is provided by the observation that iNOS-containing hypothalamic neurons, containing undetectable levels of GTPCH protein or mRNA, make direct contact with GTPCH-rich dopaminergic neurons (Hwang *et al.*, 1998). Cellular transport mechanisms for reduced pterins have not been described.

The BH₄ Requirement for NO Synthesis

BH₄ Availability Determines the Rate of NO Synthesis and Product of NOS

Most cells in culture secrete copious quantities of NO after cytokine activation. The observation that BH₄ synthesis is induced simultaneously with NO synthesis immediately raised the possibility that the function of cytokine-induced BH₄ is to support iNOS. Using selective inhibitors of GTPCH, SR, and DHFR, it was indeed verified that *de novo* synthesis of BH₄ is essential for induction of NO production by bacterial LPS in endothelial cells (Gross *et al.*, 1991), fibroblasts (Werner *et al.*, 1991), and vascular smooth muscle cells (Gross and Levi, 1992). This dependence of NO synthesis on BH₄ was extended to cardiac myocytes (Kasai *et al.*, 1997) and to numerous other cell types, to varying

extents. In contrast, macrophage cell lines appear to have sufficient constitutive BH₄ to support maximal NOS activity (Kwon *et al.*, 1989). Thus a dependence of NOS on induced BH₄ may be cell-type specific. Importantly, the dependence of cytokine-induced NO synthesis on *de novo* BH₄ production has been confirmed in isolated vessels and animals. Depletion of BH₄ elicits a dramatic decrease in NO synthesis not only from iNOS, but also eNOS in endothelial cells and blood vessels (Kinoshita *et al.*, 1997).

In contrast to the inhibition of immunostimulant-evoked NO synthesis observed with BH₄ synthesis blockers, BH₄ repletion typically elicits an increased rate of NO synthesis by cells in culture (Gross and Levi, 1992), including human endothelial cells (Rosenkranz-Weiss *et al.*, 1997). This implies that induced levels of BH₄ remain rate limiting for NO production. Loading of some cells with exogenous BH₄ (by treatment with either BH₄ or sepiapterin) also results in earlier detection of LPS-induced NOS activity, implying that LPS-induced NOS enzyme may appear prior to the BH₄ that is required for expression of NOS catalytic activity (Gross and Levi, 1992).

BH₄ also limits LPS-induced killing and vascular dysfunction *in vivo*. Pretreatment of rats with a combination of inhibitors of BH₄ synthesis (DAHP) and pterin salvage (MTX) prevented the profound reduction in aortic contractility that arises from LPS-induced NO overproduction in the vascular wall (Gross and Levi, 1995). In another study, a GTPCH inhibitor alone was shown to attenuate LPS-induced NO synthesis and hypotension in rats (Bune *et al.*, 1996). Pretreatment with BH₄ converted a nonlethal dose of LPS in mice to a lethal dose (Gross and Levi, 1995). In the absence of LPS, BH₄ alone was without significant effect on vascular tone or animal viability. Using a greater dose of LPS that kills all mice within a 24-hour period, we observed that combined treatment with DAHP and MTX offered significant protection against killing. A BH₄ synthesis inhibitor was also shown to protect against ischemia-induced NO synthesis and hippocampal cell death in rats subjected to transient fore-brain ischemia (Cho *et al.*, 1999). Accordingly, disruption of pterin synthesis may be a useful target for pharmacological interventions intended to limit NO synthesis in pathophysiological settings associated with NO overproduction.

BH₄ Binding and Activation of NOS Catalysis

BH₄ is essential for each of the two oxygenation reactions in NOS catalysis: conversion of L-arginine (L-Arg) to hydroxy-L-arginine (OH-Arg) and conversion of OH-Arg to NO and L-citrulline. The molecular basis for the BH₄ dependence of these reactions has been controversial although clarity is in view.

To recap, for AAHs catalytic recycling of BH₄ permits the use of substrate quantities of pterin cofactor, rather than stoichiometric quantities. An essential feature of this system is that q-BH₂ is recycled to BH₄ by a distinct DHPR. Kaufman and co-workers initially rejected the view that NOS emulate AAHs in using BH₄ as a direct redox-active participant in catalysis, arguing instead for an allosteric or struc-

ture-stabilizing role for BH₄ (Giovanelli *et al.*, 1991). The principal reason for this rejection was that for each mole of BH₄ added to pure brain NOS, more than 15 mol of NO were formed in the absence of added DHPR. Dissociation of BH₄ from NOSs during catalysis is also contraindicated by the finding that NOSs bind BH₄ with three orders of magnitude greater affinity (10–100 μ M) than AAHs.

Radioligand binding experiments reveal that BH₄ binding to NOS elicits an increase in affinity for arginine-based ligands (for review, see Liu and Gross, 1996); this is consistent with an allosteric effect of pterin binding. An allosteric effect of pterin binding is also suggested from spectrophotometric and EPR studies, which show that BH₄ binding to NOS converts the heme iron from low-spin to a high-spin state (Wang *et al.*, 1995; Gorren *et al.*, 1996). A structural role for BH₄ was also indicated by the finding of an apparently important role in NOS dimer assembly (Ghosh and Stuehr, 1995). However, given that all three recombinant NOS isoforms are isolated as dimers in the absence of BH₄, it is obvious that BH₄ is not essential for dimerization. Nonetheless, stability of the NOS dimer is enhanced by bound pterin cofactor. SDS-elicited dimer dissociation was investigated to quantify the BH₄ contribution to NOS dimer stabilization (Klatt *et al.*, 1995). Although nNOS dimer is significantly stabilized by bound BH₄, this effect is not so apparent for eNOS. The crystal structure of iNOS and eNOS heme domains revealed that bound BH₄ contributes to the active site channel (Crane *et al.*, 1997; Raman *et al.*, 1998).

NOS consumption of NADPH can become uncoupled from NO synthesis, resulting in the production of superoxide and hydrogen peroxide. A unique role for BH₄ has been demonstrated in providing efficient coupling of nNOS and eNOS to NO production. Depletion of BH₄ has been shown to cause uncoupling of oxygen reduction and arginine oxidation, thereby generating superoxide and subsequently hydrogen peroxide (Pou *et al.*, 1992). Reciprocally, addition of BH₄ to eNOS was shown to increase NO production and diminish superoxide generation (Wever *et al.*, 1997). These findings were subsequently confirmed by EPR studies which revealed that recombinant nNOS and eNOS produce robust quantities of superoxide anion in the absence of BH₄ (Vivar-Vasquez *et al.*, 1998; Xia *et al.*, 1998). Production of superoxide by recombinant eNOS was blocked by heme ligands, indicating that heme, rather than FMN or FAD, is the source of superoxide. Thus, BH₄ may serve an important catalytic function for eNOS by preventing premature release of heme iron-bound dioxygen, as superoxide anion. Reasonable mechanisms whereby BH₄ might preserve bound oxygen on eNOS include a direct or allosteric-induced modification in heme-iron redox potential.

Despite a potential allosteric role of BH₄ as a NOS cofactor, a redox function for BH₄ is appealing, and it is consistent with several findings. First, although various tetrahydropterins have been reported to possess NOS cofactor activity (Riethmüller *et al.*, 1999), a dihydropterin has never been shown to support catalysis. Moreover, tetrahydropterins with

modifications that would predictably cause them to be redox-silent, such as 5-deazatetrahydropterin (Hevel and Marletta, 1992) and 4-aminotetrahydropterin (Werner *et al.*, 1996), are devoid of NOS cofactor activity. Finally, redox-inactive pterin analogs can mimic the effects of BH₄ on NOS dimerization, substrate affinity, and heme spin state but fail to support NOS catalysis. It is also notable that BH₄-deficient NOS is largely uncoupled, producing superoxide rather than NO. This may reflect the premature release of heme-bound O₂ under conditions where BH₄ is unavailable to donate a catalytically required electron. Thus, putative allosteric effects of pterins may be necessary for NOS function, but they are clearly insufficient to explain cofactor function. Importantly, the NOS oxygenase domain crystal structure reveals that bound BH₄ is positioned in a manner which could accommodate electron donation from the pterin to heme iron, through pterin N-3/O-4 contact with the heme pyrrole A propionate group (Crane *et al.*, 1998; Raman *et al.*, 1998). Additional structural features of the NOS–pterin interaction and recent spectral findings strongly infer a redox function of BH₄; these findings are discussed below.

Structural Interactions of Pterin Cofactor with NOSs

Crystal structures of the heme domains of iNOS (Crane *et al.*, 1998; Fischmann *et al.*, 1999), eNOS (Raman *et al.*, 1998; Fischmann *et al.*, 1999), and nNOS (Raman *et al.*, 2000) all reveal a nearly identical mode of pteridine cofactor binding. Three structural features stand out as hallmarks in describing the binding mode of BH₄ with NOS (Fig. 5): (i) an extensive network of hydrogen bonds and van der Waals contacts hold the pterin cofactor in place; (ii) the heme propionate and pterin pyrimadone (amine at C-2 and N-3) make direct interactions; and (iii) aromatic side chains stack around the pterin ring. These features of pterin binding are now considered in more detail.

First, the large number of hydrogen-bonding (>12) and nonbonded contacts between the protein and the cofactor illustrates why BH₄ is bound with high affinity ($K_d \approx 30$ nM) to NOS (Werner-Felmayer and Gross, 1996). In addition, the bound cofactor, for the most part, is sequestered from the bulk solvent. This mode of binding is quite different from that observed in the case of TH (Goodwill *et al.*, 1998), in which BH₄ is expected to largely retain solvent accessibility and in which binding affinity is orders of magnitude weaker than with NOSs. The structure of TH complexed with 7,8-dihydrobiopterin (Fig. 6A) provides insight into how pterins are recognized by enzymes other than NOS, and it also illustrates the reasons for the relatively poor binding affinity.

Second, of the two rings that comprise the pteridine, namely, pyrimidine and pyrazine, it appears that the pyrimidine moiety incorporates the signature for molecular recognition by NOS. This conclusion is based on the observation that a heme propionate is used to perform the recognition in NOS instead of the protein carboxylates (Glu and Asp) typically utilized by other pterin-binding enzymes. The use of protein carboxylates in pyrimidine recognition has a rich his-

Figure 5 High-resolution structures of BH_4 bound to eNOS. (A) Key hydrogen-bonded (dashed lines) and van der Waals contacts between the cofactor and the protein are depicted. Light shading around the cofactor corresponds to the solvent-accessible surface. Darker shading represents the region of poor solvent accessibility. The glycerol bound next to the cofactor derives from the cryoprotectant cocktail used during data collection. Solvent molecules are expected to replace glycerol in the native state of the enzyme. An (A) or (B) next to the label corresponds to the subunit with which a given residue is associated. (B) A schematic representation of the cross talk between the active and cofactor sites in NOS. Both stacking (at the BH_4 site) and hydrogen-bonding interactions entertained by the substrate and cofactor are shown. The “B” next to F462 identifies this residue to be part of the second subunit in the NOS dimer. See color insert.

Figure 5 (continued)

tory. The GTPase superfamily (Bourne *et al.*, 1991; Varnum *et al.*, 1995) is a prime example in which a conserved protein carboxylate mediates recognition of GTP via its pyrimidine component. Interestingly, each of the three enzymes of the *de novo* BH₄ synthetic pathway—GTPCH, PTPS, and SR—bind to their substrates—GTP, dihydroneopterin triphosphate, and 6-pyruvoyltetrahydropterin, respectively—via a conserved protein carboxylate (Auerbach *et al.*, 1997) (see Fig. 6B). The key role of a conserved protein carboxylate in recognizing pterin is also observed in DHFR (Bolin *et al.*, 1982), thymidylate synthase (Birdsall *et al.*, 1996), 7,8-dihydroneopterin aldolase (Hennig *et al.*, 1998), and dihydropteroate synthase (Hampele *et al.*, 1997). There are clear exceptions to this widespread scheme of molecular recognition; however, TH, which requires BH₄ as an obligatory cofactor, does not incorporate a protein carboxylate to recognize the guanidinium function. A similar case is observed for PCD (Cronk *et al.*, 1996) and DHPR (Varughese *et al.*, 1992). An interesting question is why TH, PCD, and DHPR do not utilize a protein carboxylate to lock the pyrimadone in place; plausible functional reasons are offered in the next section. The ability of an enzyme to utilize a carboxylate to perform recognition of pterin extends even to enzymes dependent on molybdopterin cofactor, for example, aldehyde ferredoxin oxidoreductase (Chan *et al.*, 1995). It is also worth pointing out that the affinity of carboxylic acids toward the pyrimadone has been characterized in detail by direct chemical investigations (Etter and Adsmond, 1990).

Third, aromatic amino acids stack on either side of the pterin cofactor in NOS. Interestingly, one of the stacking aromatic side chains (e.g., Phe-462 in bovine eNOS) stems from the second subunit. Such a flanking arrangement of aromatics around a pterin is not unique to NOS and has been observed in other systems, including thymidylate synthase (Birdsall *et al.*, 1996) and ricin (Yan *et al.*, 1997). Considering that the high N/C ratio affords the pteridine ring system greatly reduced aromaticity, and therefore a weakened π -

electron layer, it is intriguing that aromatics stack around pteridine compounds.

Structural Insights into the Role of Pterin Cofactor in NOS Catalysis

What is the role of BH₄ in NO biosynthesis? Does it play a structural or functional role? That BH₄ plays a catalytic function is implicit in the structure of eNOS. Raman *et al.* (1998) compared pterin-bound and pterin-free crystal structures, revealing that cofactor binding is not essential for maintaining the quaternary structure of NOS. In addition, there were no detectable conformational differences in the pterin binding site with and without bound cofactor. If BH₄ does not play a dominant structural role, it should play a catalytic role, and it is worth reiterating the conditions under which NOS catalysis is supported by pterin cofactor: (a) NO generation does not occur in the absence of BH₄; (b) only the four-electron reduced pterin, BH₄, will, *in toto*, function as a cofactor; (c) the two-electron oxidized pterin species (BH₂) is not a cofactor, although it is capable of binding to the pterin cofactor site; and (d) whereas the dihydroxypropyl side-chain substitution at the 6 position on the pteridine dictates the stereospecificity of BH₄ recognition, it is not essential for cofactor function.

In approaching the problem of understanding the catalytic function of BH₄ in NO biosynthesis, it is informative to consider similarities with other enzymes where reduced pterin cofactors are a *sine qua non* for catalysis. As summarized earlier, pteridines function as cofactors in a wide variety of enzyme-catalyzed reactions. In particular, tetrahydrofolate (bacterial and eukaryotes) and tetrahydromethanopterin (archaea) mediate transfer of one-carbon fragments. BH₄ is utilized as a cofactor by alkylglyceryl monooxygenases and in the hydroxylation of aromatic amino acids; molybdopterin is a cofactor in a wide variety of redox enzymes. Of the BH₄-utilizing enzymes, AAHs have been most extensively studied with respect to cofactor function, and they serve as a useful reference to compare and contrast the role of pterin in NOSs. AAH requires an enzyme-bound nonheme Fe²⁺ for activating molecular oxygen and hydroxylating the aromatic ring of the amino acid substrate. Molecular oxygen, however, oxidizes the Fe²⁺ to Fe³⁺. BH₄ can reduce the inactive Fe³⁺ enzyme back to the catalytically competent Fe²⁺ state, facilitating catalysis. During this process BH₄ is oxidized to 4a-hydroxytetrahydrobiopterin and released from the enzyme. The carbinolamine is then dehydrated by PCD (to qBH₂, see earlier), which is then reduced by NADH-dependent DHPR to regenerate BH₄. The crystal structure of TH (Goodwill *et al.*, 1998) complexed with 7,8-BH₂ reveals the BH₄ binding site in the enzyme. The crystal structure of TH also reveals that a nonheme iron is located within 5.6 Å of the 4a site of BH₄, which is the position of oxidation. When the pterin binding sites of TH and NOS are compared, the dissimilarities are most conspicuous. First, the distance between the heme iron and 4a of BH₄ in NOS is markedly greater in NOS (12.4 Å). Second, the pyrimadone in TH is

Figure 6 Structures of tyrosine hydroxylase and sepiapterin reductase with bound pterin. (A) The cofactor site of TH is depicted in complex with 7,8- BH_2 . Notice that the amines at C-2 and N-3 do not interact with the enzyme, in contrast to the case for SR, shown in (B). The distance of separation between the catalytic Fe(II) and N-5 of the cofactor is 5.6 Å. A nonheme iron, however, is not part of the catalytic NOS heme domain structure. (B) The substrate binding site of SR is depicted in complex with biopterin. Notice the key Asp-258 side-chain carboxylate mediating the specific recognition of the pyrimadone. See color insert. (*Continues*)

not protected by hydrogen bonds as it is in NOS, and an extensive hydrogen-bonding network of pterin contacts is absent from TH. It has been known for some time that the highly activated pyrimidine nucleus is responsible for facile oxidation of BH_4 . Therefore, it is reasonable that N-3 and N-5 of pterin are not tied up in strong hydrogen-bonding interactions in TH, but rather are available for promoting the pterin ring oxidation essential to catalysis. A similar scenario

is seen in the crystal structure of BH_2 complexed PCD (Cronk *et al.*, 1996). The crystal structure of DHPR—albeit uncomplexed with q- BH_2 —and associated biochemical studies suggest that the pyrimadone is free in the pterin-bound enzyme (Varughese *et al.*, 1992). When these observations in related enzyme systems are compared with NOS, three key differences emerge: (a) a nonheme iron is absent in NOS, and therefore BH_4 does not undergo oxidation to

Figure 6 (continued)

the 4a-hydroxy-BH₄ state; (b) the pterin cofactor of NOS, unlike that of AAH, is nondissociable during catalysis, as evidenced by the plethora of interactions it entertains and its observed high affinity for enzyme binding; and (c) the indispensable requirement for a tetrahydropterin cofactor argues in favor of a novel redox mechanism for the participation of BH₄ in the catalytic steps leading to NO biosynthesis.

The precise mechanism by which BH₄ functions in NOS catalysis is uncertain, although the crystal structure of pterin-free eNOS has supported a mechanistic proposal that could be experimentally tested. Raman *et al.* (1998) had solved two pterin-free eNOS heme domain crystal structures: (a) a structure with substrate bound at the active site and (b) a structure with a potent inhibitor, *S*-ethylisothiourea (SEITU), bound at the active site. When the substrate is bound at the active site, the pterin site was empty with the exception of solvent molecules present. In the SEITU-complexed state, however, the substrate itself was bound to the BH₄ site (see

Figure 7 Cofactor mimicry by substrate L-Arg, when *S*-ethylisothiourea (SEITU) occupies the substrate site. Hydrogen bonds are shown as dotted lines, and red spheres correspond to water molecules. The mode of L-Arg binding at the pterin site exquisitely mimics that of BH₄ and serves as the basis for the structure-based proposal for the involvement of pterin radical in NOS catalysis. See color insert.

Fig. 7). This is interesting because the ability of the pterin site to bind other molecules, particularly the substrate, was unknown from earlier biochemical studies. L-Arginine bound at the pterin site closely mimics the BH₄ binding mode, with the guanidinium of the substrate making hydrogen-bonding contacts with the heme propionate. The pyrimidine ring of BH₄ has a built-in guanidinium function (see earlier), and the molecular recognition of an L-Arg guanidinium at the pterin binding site reveals that occupancy by a strong base can be accommodated. The recruitment of L-Arg (pK_a of the guanidinium 12.48) to the pterin site further suggests that the BH₄ binding site may be poised to stabilize a positively charged state of the pterin ring. Thus, a fully protonated pterin can potentially bind to the pterin site of NOS. Complete protonation of BH₄ would restrict the lone pair reactivity on N-5 of the pyrazine ring and favor the ability to generate a trihydropterin radical via one-electron oxidation. On the basis of rapid reaction kinetics, Bec and colleagues (1998) proposed the formation of a pterin radical in nNOS, which is in complete agreement with the structure-based proposal presented here. More recently, Hurshman *et al.* (1999) have trapped the trihydropterin radical and conclude that BH₄ indeed participates in the electron transfer reactions of NOS catalysis. Details on the role of pterin radical in NOS function are discussed elsewhere (Raman *et al.*, 2000).

Does the identification of a pterin radical provide sufficient information to describe the NO biosynthetic machinery? The simple answer to this question is no! There are, however, structural features that are intriguing. First, the heme propionate that hydrogen bonds to the pyrimadone of BH₄ is also hydrogen-bonded to the primary amino group of substrate, L-Arg. Second, the primary amino group of L-Arg

Figure 8 Close proximity between flavin adenine dinucleotide and the heme prosthetic group in bacterial flavohemoglobin. The dashed line corresponds to the distance of separation between FAD and the propionate. A water molecule is equidistant between the two. See color insert.

is hydrogen bonded to Glu-363 (bovine eNOS), which also holds the substrate guanidinium in place. Thus, electron transfer can be facilitated by the direct link between the cofactor, heme, and the substrate. Although direct interaction between a pterin cofactor and heme prosthetic group is without precedent, function in electron transfer is in accord with knowledge of bacterial flavohemoglobins (Ermler *et al.*, 1995). Notably, electron transfer from FAD to heme in flavohemoglobin is effective in a configuration in which FAD is less than 6 Å distant from a heme propionate group (Fig. 8). Thus, both circumstantial and direct lines of evidence implicate an electron transfer role for pterin in NO biosynthesis.

Despite the fundamental role of BH₄ in the regulation and mediation of NO synthesis, the function of BH₄ in NOS catalysis remains largely an enigma. Nonetheless, the elusive role of BH₄ will surely be defined in the near future, promising cardinal advance in our understanding of NOS enzymology.

Regulation of Arginine Availability and Its Impact on NO Synthesis

Sidney M. Morris, Jr.

*Department of Molecular Genetics and Biochemistry
University of Pittsburgh School of Medicine
Pittsburgh, Pennsylvania*

BECAUSE ARGININE IS THE ONLY PHYSIOLOGICAL SOURCE OF THE NITROGEN ATOM IN NITRIC OXIDE (NO), ENZYMATIC REACTIONS AND OTHER PROCESSES THAT REGULATE THE AVAILABILITY OF THIS AMINO ACID PLAY CRUCIAL ROLES IN REGULATING RATES OF NO SYNTHESIS IN HEALTH AND DISEASE. THE PROCESSES OF ARGININE BIOSYNTHESIS, CATABOLISM, AND TRANSPORT ARE ESPECIALLY IMPORTANT IN MODULATING BOTH INTRACELLULAR AND PLASMA LEVELS OF ARGININE. THE KEY PLAYERS IN THESE PROCESSES ARE ARGININOSUCCINATE SYNTHASE, THE ARGINASES, AND THE CATIONIC AMINO ACID TRANSPORTERS (CATs), RESPECTIVELY. THEIR EXPRESSION NOT ONLY VARIES AMONG DIFFERENT CELL TYPES BUT IS DYNAMICALLY MODULATED BY BACTERIAL LIPOPOLYSACCHARIDE, CYTOKINES, AND OTHER AGENTS. IN PARTICULAR, ARGININOSUCCINATE SYNTHASE AND THE CATs ARE GENERALLY COINDUCED WITH INFLAMMATORY NITRIC OXIDE SYNTHASE (iNOS), APPARENTLY TO MAXIMIZE CELLULAR CAPACITY FOR NO SYNTHESIS. THE METABOLIC ROLES AND EXPRESSION OF THE ARGINASES, WHICH COMPETE WITH THE NOS ENZYMES FOR A COMMON SUBSTRATE, ARE MORE COMPLEX AND INCOMPLETELY UNDERSTOOD. THE ARGININE METABOLITE AGMATINE, RECENTLY DISCOVERED TO BE SYNTHESIZED BY MAMMALS, HAS POTENTIAL FOR INHIBITING NO SYNTHESIS, BUT ITS FUNCTION *IN VIVO* REMAINS TO BE ESTABLISHED. AS VIRTUALLY ALL THE ENZYMES OF ARGININE METABOLISM, INCLUDING THE NOS ISOZYMES, CAN BE EXPRESSED WITHIN THE SAME CELL, THE COMPLEX INTERPLAY BETWEEN THE OFTEN CONFLICTING OR COMPETING REACTIONS REPRESENTS A CONSIDERABLE CHALLENGE TO OUR ABILITY TO UNDERSTAND THE FACTORS THAT CONTROL NO SYNTHESIS IN DIFFERENT CELL TYPES.

Introduction

The regulation of nitric oxide (NO) synthesis has proved to be remarkably complex. As described elsewhere in this volume, the synthesis of the nitric oxide synthase (NOS) isoforms and their cofactors, as well as NOS activity, is highly regulated, and our understanding of these processes is far from complete. The ever-burgeoning studies of NO synthesis during the 1990s have spurred a growing appreciation of and interest in the complex metabolism of arginine.

Prior to 1987, this amino acid was most commonly recognized as a metabolite of the urea cycle and as a substrate in creatine biosynthesis. Following the discovery that arginine is the only physiologically significant source of the nitrogen atom in NO, interest in other aspects of arginine metabolism intensified.

Availability of arginine for NO synthesis is determined by five factors: exogenous supply (dietary intake by intact animals or concentration in the medium used to culture cells), endogenous release of arginine via protein degradation,

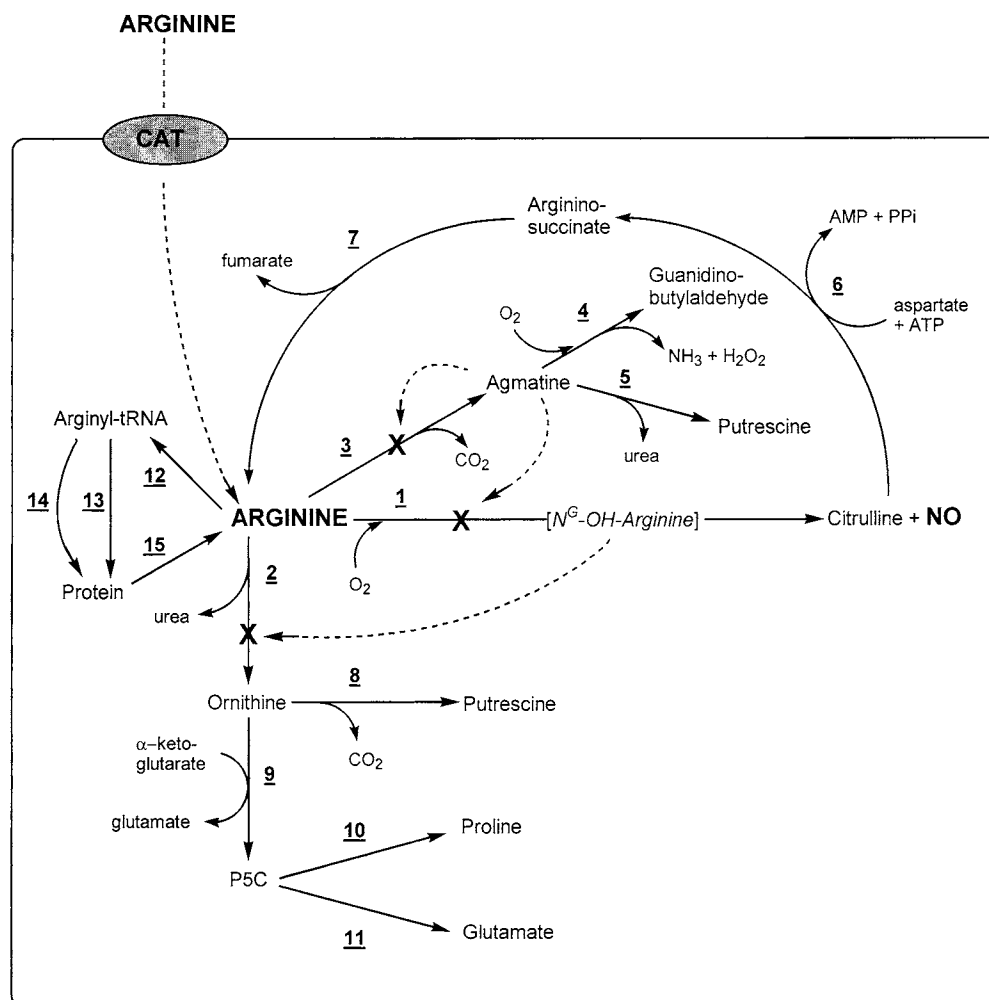

Figure 1 Overview of arginine metabolism in nonhepatic cells. For the sake of simplicity, subcellular compartments, multiple enzyme isoforms, and enzyme cofactors are not depicted. Structures of key metabolites are shown in Fig. 2. Key to enzymes: 1, NOS; 2, arginase; 3, arginine decarboxylase; 4, diamine oxidase; 5, agmatinase; 6, argininosuccinate synthase; 7, argininosuccinate lyase; 8, ornithine decarboxylase; 9, ornithine aminotransferase; 10, P5C reductase; 11, P5C dehydrogenase; 12, arginyl-tRNA synthetase; 13, protein synthesis; 14, arginyl-tRNA-protein transferase; 15, proteases. Abbreviations and symbols: P5C, Δ^1 -pyrroline-5-carboxylate; CAT, cationic amino acid transporter.

endogenous arginine synthesis, arginine catabolism, and arginine transport. Enzymatic reactions involved in each of these processes are depicted in Fig. 1. The last four processes regulate availability of arginine at two levels: by controlling plasma arginine levels in the intact animal and by regulating the intracellular supply of arginine for NO synthesis in individual cell types. Complexity arises from the fact that relative contributions of each of these processes to overall arginine availability are not the same in every cell type, and they can vary considerably during development and in response to various stimuli, including those that regulate NO synthesis. In addition, the various enzymatic reactions are not always independent, that is, the product or intermediate of one enzyme may inhibit the activity of a different enzyme, the most notable example being inhibition of arginase by N^G -hydroxyarginine, an intermediate in NO synthesis (Fig. 1).

The structural similarity between arginine and several of its metabolites (Fig. 2) might suggest that several of these compounds could serve as substrates for NO synthesis, but the NOS enzymes are quite selective in abstracting one of the two chemically equivalent nitrogen atoms in the guanidino group of arginine. Agmatine, guanidinobutylaldehyde, and guanidinoacetate retain the guanidino group found in arginine itself, but they have very little or no activity as substrates for NO synthesis. N^G -Hydroxyarginine, a relatively stable intermediate in NO synthesis, is a substrate for NOS when provided exogenously to cells, but, unlike arginine, it is a potent inhibitor of arginase (Fig. 1). Only the L-enantiomers of arginine, its metabolites, or analogs are recognized by the NOS enzymes as substrates or inhibitors.

This chapter reviews the concept that competing enzymatic reactions and other processes which regulate arginine

Figure 2 Structures of arginine and arginine-derived metabolites. Guanidinoacetate, derived from arginine and glycine, is the first intermediate in creatine biosynthesis.

availability can play important roles in determining rates of NO synthesis. The primary focus will be on arginine synthesis, with brief mention of the roles of arginine transport and the arginases because these topics will be considered in depth in subsequent chapters. Possible roles of agmatine, an arginine metabolite synthesized in mammalian cells, also will be noted. Some aspects of arginine metabolism that are represented in Fig. 1 will not be discussed because of inadequate information specifically relating these processes to NO synthesis. These reactions include ubiquitous processes involved in protein synthesis (reactions 12 and 13), posttranslational modification (reaction 14), and degradation (reaction 15). Although high-level production of NO in cells induced to express inflammatory NOS (iNOS) can result in inhibition of protein synthesis, no studies have evaluated the roles of protein synthesis and degradation in regulating availability of arginine for NO synthesis within specific cell types. This chapter also will not consider potential roles of arginine:glycine amidinotransferase, an arginine-requiring enzyme that catalyzes the first step in creatine biosynthesis (not illustrated), because it is expressed only in a limited number of specialized cell types and has not been shown to regulate arginine availability for NO synthesis.

Exogenous Arginine and Arginine Homeostasis

Owing to endogenous synthesis, arginine is classified as a conditionally essential dietary amino acid for many adult mammals, including humans and rodents. Consequently, feeding these species an arginine-free diet has relatively little impact on plasma arginine levels. However, in immature, growing animals and in cases where functions of the major organs involved in arginine synthesis (i.e., the small intestine and kidneys) have been compromised by injury, infection, or surgical resection, endogenous synthesis is insufficient to meet the needs of the organism, and arginine therefore is required in the diet.

Arginine is an essential dietary amino acid for some species, including chickens and carnivores such as cats, ferrets, and dogs. Owing to the dietary requirement, it is possible to modulate plasma arginine levels in these creatures over a wider range than in humans and rodents by varying dietary arginine intake. Interestingly, this biological property has not been exploited to evaluate the impact of varying plasma arginine levels on NO synthesis in these animals.

Plasma arginine levels for healthy adult mice and humans are approximately 100 μM . In contrast, concentrations of arginine in standard tissue culture media are considerably higher, for example, 400 μM for DMEM medium and 1150 μM for RPMI 1640 medium. Consequently, in cultured cells with active arginine transport systems, rates of NO synthesis may be much higher than *in vivo*, possibly giving rise to effects which are not physiological. Moreover, cultured cells are not continuously perfused with fresh medium and substrates, so that availability of arginine declines with time in culture. As a result, total NO production in iNOS-expressing cells during, for example, an overnight incubation may be more a reflection of the ratio of the volume of culture medium to total cell number than of the capacity of the cells to produce NO during the incubation period. These points should be taken into consideration when extrapolating results obtained with cultured cells to *in vivo* conditions.

Plasma arginine levels can decline by as much as 50–60% during sepsis, but the basis for this is not known. Although it is tempting to speculate that this is the consequence of iNOS induction, it has become clear that the arginases are also induced by inflammatory stimuli such as bacterial lipopolysaccharide (LPS), so these enzymes may contribute significantly to the reduction in plasma arginine levels during sepsis. Expression of plasma arginine transporters also is increased by inflammatory stimuli, thus enhancing capacity for arginine clearance. In short, it is likely that changes in multiple components of arginine metabolism contribute to the decline in plasma arginine levels in septic individuals.

Arginine homeostasis is maintained by a balance between dietary arginine intake, arginine production (synthesis plus release from degraded protein), and arginine degradation. Although the high capacity for endogenous arginine synthesis limits the impact of an arginine-free diet on plasma arginine levels in most mammals, elevated dietary intake can exceed the capacity for arginine degradation. Thus, it is

possible to double or triple plasma arginine levels by providing supplemental arginine in the diet or drinking water.

Regulation of arginine homeostasis is poorly understood. On the basis of metabolic labeling studies, it has been proposed that arginine degradation and/or dietary arginine intake, rather than arginine synthesis, are the primary regulators of arginine homeostasis. Consistent with this hypothesis, preliminary studies have shown that plasma arginine levels in mice homozygous for a “knockout” of the type II arginase gene are severalfold higher than in wild-type mice. This result indicates not only that type II arginase plays a major role in arginine homeostasis, but also that compensatory changes in arginine biosynthesis or type I arginase expression, if any, are not sufficient to restore normal plasma arginine values.

Arginine Synthesis

Whole Body

Net arginine synthesis *in vivo* is accomplished primarily by a collaboration between intestinal epithelial cells, which utilize glutamate and glutamine to synthesize citrulline, and renal proximal tubular cells, which take up citrulline and convert it to arginine. In fact, the renal tubular cells are responsible for approximately 60% of net arginine synthesis in adult mammals. Rates of renal arginine synthesis in adults are limited by the supply of citrulline rather than by renal capacity for converting citrulline to arginine. Plasma levels of citrulline, produced primarily by the small intestine, are normally 30–40 μM . High rates of arginine synthesis occur also within the urea cycle in liver, but there is little or no net production of arginine because newly synthesized arginine is immediately hydrolyzed to ornithine and urea. It is important to recognize that net arginine synthesis accounts for only 5–15% of total plasma arginine flux in healthy adults, indicating that most of the arginine entering the plasma pool is derived from protein degradation and diet. Endogenous arginine synthesis can contribute up to 30% of the total plasma arginine flux in immature growing animals.

The Citrulline–NO Cycle

Although the highest rates of net arginine synthesis occur in renal tubules, the capability for synthesizing arginine from citrulline, one of the two products of the NOS-catalyzed reaction, exists to some degree in virtually all cells. This led eventually to appreciation of the possibility that synthesis of NO and arginine could be coupled in a pathway termed the arginine–citrulline cycle or the citrulline–NO cycle (Fig. 3), such that citrulline is recycled to arginine. This pathway is analogous to the classic urea cycle in liver, which also includes argininosuccinate synthase and argininosuccinate lyase (Fig. 3). The only route other than NOS for producing citrulline in vertebrates is via the sequential action of carbamyl phosphate synthetase I and ornithine carbamyltransfer-

ase (Fig. 3), which are expressed only in parenchymal hepatocytes, epithelial cells of the small intestine, or in certain hepatoma or intestinal epithelial cell lines.

The conversion of citrulline to arginine occurs via the sequential action of argininosuccinate synthase and argininosuccinate lyase (Fig. 3). Argininosuccinate synthase exists as a tetramer of four identical subunits with a subunit molecular weight of approximately 46 kDa. Argininosuccinate lyase also is comprised of four identical subunits, with a subunit molecular weight of approximately 51 kDa. No isozymes or posttranslationally modified forms of either enzyme are known to occur. The citrulline-to-arginine conversion requires aspartate as the nitrogen donor and energy in the form of ATP. Figure 3 indicates that the aspartate used in the citrulline–NO cycle is regenerated from fumarate as is commonly depicted for the urea cycle, but there is no direct evidence for this. The hydrolysis of ATP to AMP and inorganic phosphate represents an energy requirement of two high-energy phosphate bonds for each nitrogen atom which is replenished in the citrulline–NO cycle. A practical consequence of this is the fact that the presence of argininosuccinate synthase should not interfere with *in vitro* assays of NOS activity which measure conversion of arginine to citrulline unless appreciable amounts of both ATP and aspartate also are present in the assay.

The presence of a citrulline–NO cycle is usually inferred if the substitution of citrulline for arginine in culture media supports cellular NO synthesis, but this does not necessarily indicate that a major fraction of NOS-produced citrulline is recycled into arginine when cells are incubated in the presence of arginine. In healthy adult humans, for example, about half of the arginine used for NO synthesis is derived from the plasma arginine pool, the remainder coming from intracellular protein degradation and endogenous arginine synthesis. Although limited, the available data indicate that efficiency of the citrulline–NO cycle varies from one cell type to another, but in no case has the efficiency been shown to approach that of the urea cycle. This is clearly evident from the fact that citrulline accumulates in the medium of NO-producing cells cultured in the presence of arginine. The low efficiency may reflect the K_m of argininosuccinate synthase for citrulline, which is approximately 40–70 μM . Consequently, if the rate of cellular NO synthesis is modest and if citrulline is transported across the plasma membrane at an appreciable rate, recycling of citrulline to arginine would be expected to be inefficient if the reactions in the citrulline–NO cycle are diffusion-controlled. However, cycle efficiency can be enhanced if the enzymes in the pathway are in close apposition within the cell. Both argininosuccinate synthase and argininosuccinate lyase are found primarily in the cytosolic fraction of cell homogenates, but there is evidence that they are associated with mitochondria in hepatocytes and smooth muscle cells. The mitochondrial association in hepatocytes undoubtedly contributes to the high efficiency of metabolite “channeling” within the urea cycle. There is one report that iNOS, argininosuccinate synthase, and argininosuccinate lyase are colocalized on or near mitochondria in

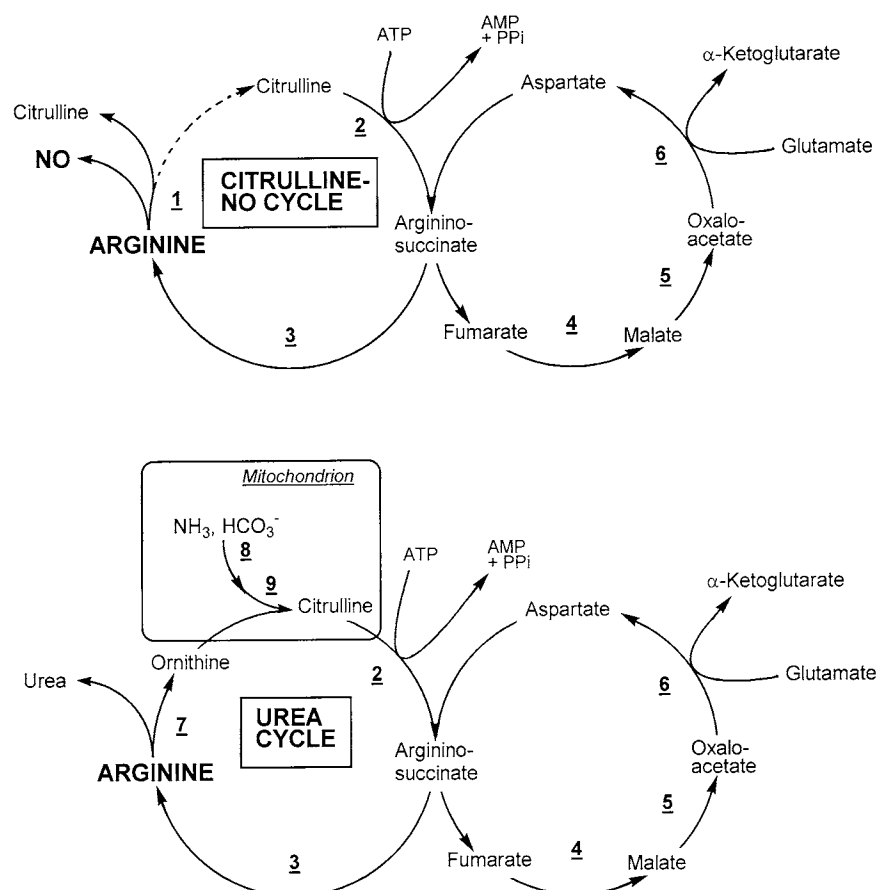

Figure 3 The citrulline–NO cycle and the urea cycle. The dashed line indicates that only a fraction of citrulline produced by NOS is recycled via the citrulline–NO cycle (adapted from Fig. 5 of Nussler *et al.*, 1994). Key to enzymes: 1, NOS; 2, argininosuccinate synthase; 3, argininosuccinate lyase; 4, fumarase; 5, malate dehydrogenase; 6, aspartate aminotransferase; 7, arginase (type I); 8, carbamyl phosphate synthetase I; 9, ornithine carbamyltransferase. Two ATP are required for reaction 8 in the urea cycle.

vascular smooth muscle cells, possibly to maximize efficiency of the citrulline–NO cycle. Whether such colocalization is a common feature of NO-producing cells remains to be determined.

Argininosuccinate synthase—but rarely argininosuccinate lyase—is coincided with iNOS in nearly all mammalian cell lines and primary cultured cells examined to date (Table I). Argininosuccinate synthase and iNOS are induced in primary cultures of mixed neural cell types but are not coexpressed within the same cells, suggesting that an intercellular citrulline–NO cycle may exist in some cell populations. Virtually any stimulus that has been shown to induce iNOS also induces argininosuccinate synthase (Table I; Fig. 4). As basal expression of argininosuccinate synthase varies considerably from one cell type to another, the magnitude of argininosuccinate synthase induction following stimulation with LPS or cytokines varies enormously. In cells with high basal expression of argininosuccinate synthase, for example, expression may be induced only two- or threefold, whereas expression may be induced by as much as 50-fold in cells with low basal expression. Responses in vascular smooth muscle cells illus-

trate the remarkable induction of argininosuccinate synthase expression possible in cells with low basal expression (Fig. 4). One characteristic of iNOS expression is the dramatic synergism in its induction by combinations of specific agents. This feature is shared also by argininosuccinate synthase (e.g., compare the response to LPS + TNF α versus responses to LPS or TNF α alone in Fig. 4). As in cultured cells, argininosuccinate synthase and iNOS are co-induced in heart, lung, kidney, and spleen of LPS-treated rats. The response is unlike that of cultured cells, however, in that argininosuccinate lyase also is induced in these organs. The basis for the induction of argininosuccinate lyase *in vivo* but not in cultured cells is unknown.

The induction of argininosuccinate synthase rather than of argininosuccinate lyase in stimulated cells is consistent with the assumption that the former enzyme catalyzes the “rate-limiting” step in the conversion of citrulline to arginine. This assumption is based primarily on measurements of enzyme activities in cell homogenates, but it has not been established that this is indeed the case in intact cells. Without knowing the activity of argininosuccinate lyase and the

availability of aspartate and ATP (Fig. 3) for the cells under investigation, it cannot be assumed that increases in expression of argininosuccinate synthase necessarily represent equivalent increases in cellular rates of citrulline recycling to arginine. Argininosuccinate synthase is subject to inhi-

bition by arginine, thus raising the possibility that the citrulline–NO cycle may function more efficiently at low rather than high arginine concentrations. However, the inhibition constant for arginine is in the millimolar range, so appreciable inhibition will not occur unless intracellular arginine concentrations are in this range.

A special case of arginine metabolism is represented by hepatocytes, which not only express the urea cycle but also can be induced to express iNOS. As argininosuccinate synthase and argininosuccinate lyase normally are highly expressed in liver, their expression does not increase further when iNOS is induced. High rates of arginine synthesis occur within the urea cycle, but the enzymes in this pathway constitute a metabolon whereby the product of each reaction is efficiently channeled to the next enzyme in the pathway. As a consequence of this tight channeling, little or no arginine produced within the urea cycle can be utilized by iNOS. Most of the arginine for hepatic NO synthesis is probably generated by intracellular protein degradation.

Inhibition of arginine synthesis by nonhormonal stimuli has been observed in some NO-producing cells. For example, glutamine inhibits arginine synthesis in endothelial cells, cerebral perivascular neural tissue, and rat peritoneal macrophages but not in a murine macrophage line. This inhibition occurs via competitive inhibition of citrulline uptake and by decreasing activity of argininosuccinate synthase by an unknown mechanism. Hypoxia also decreases activity of argininosuccinate synthase in endothelial cells and inhibits its induction by LPS.

The contribution of endogenous arginine synthesis to NO synthesis has been difficult to evaluate because of the lack of NO-producing cells which do not express these enzymes or of potent, highly specific inhibitors of argininosuccinate

Figure 4 Expression of iNOS, argininosuccinate synthase (AS), and argininosuccinate lyase (AL) in rat pulmonary artery smooth muscle cells. synthase or argininosuccinate lyase. α -Methyl-D,L-aspartate, an inhibitor of argininosuccinate synthase in the test tube, blocks NO synthesis in stimulated cells when citrulline is substituted for arginine. However, it also inhibits NO synthesis in stimulated cells even when ample arginine is provided, thus calling into question the specificity of its inhibitory effects in intact cells. Similar difficulties in interpretation of results arise from use of the general transaminase inhibitor (aminoxy)acetic acid, which inhibits NO synthesis when stimulated cells are cultured in the presence of either arginine or citrulline. The generation of homozygous genetic knock outs of argininosuccinate synthase or argininosuccinate lyase expression has not proved to be useful because these enzymes are essential components of the urea cycle (Fig. 3), and such knockout animals therefore die from hyperammonemia in the perinatal period. An alternative strategy is to enhance cellular arginine biosynthetic capacity and determine its effect on NO production. Using this approach, vascular smooth muscle cells that had been transfected to overexpress argininosuccinate synthase were found to produce more NO following cytokine stimulation than did control cells, thus providing further evidence for the notion that the citrulline–NO cycle can indeed play an important role in regulation of NO synthesis rates.

Arginase

As the interrelationships between arginase expression and NO synthesis are discussed in more detail in the next chapter, by Mori and Gotoh, this topic will be considered only briefly here. First, it is essential to recognize that two isozymes of arginase exist. Type I arginase is cytosolic and is best known as a component of the urea cycle within hepatocytes. Type II arginase, the product of a separate arginase gene, is localized within the mitochondrial matrix and is expressed by a wide variety of cell types. The different subcellular locations of the arginases may represent a mechanism for directing ornithine to different end products, as indicated in Fig. 5.

With regard to NO synthesis, interest in the arginases has grown because of the facts that both NOS and the arginases utilize arginine as substrate and that both enzyme activities are often expressed within the same cells. This initially led to the hypothesis that, owing to competition for a common substrate, simultaneous expression of arginase(s) and NOS—particularly iNOS—may result in reduced production of NO (and possibly of ornithine and urea as well).

Consideration of the properties of these two sets of enzymes lends credence to this notion: For the NOS enzymes, the K_m for arginine is in the 2–20 μM range, but the V_{max} is approximately 1 $\mu\text{mol}/\text{min}/\text{mg}$; in the case of the arginases, the K_m is much higher—approximately 2–20 mM—but the estimated V_{max} is about 1400 $\mu\text{mol}/\text{min}/\text{mg}$. Thus, rates of arginine consumption by equivalent levels of NOS and arginase should be similar at low arginine concentrations but relative consumption of arginine by the arginases would be expected to be predominant at higher arginine concentrations, such as the concentrations found in tissue culture media. Indeed, early studies of arginine metabolism by activated murine macrophages found that the majority of arginine consumed was for the production of urea rather than of NO, and subsequent studies found that inhibition of arginase resulted in increased NO production by activated macrophages. Recent work has shown, however, that interactions between the NOS and arginase enzymes are more complicated than simple competition for substrate. For example, appreciable amounts of N^G -hydroxyarginine, an intermediate in NO synthesis, are released from iNOS in intact cells. As this compound is one of the most potent arginase inhibitors yet discovered, cells with high NO synthesis rates also produce N^G -hydroxyarginine in quantities sufficient to inhibit arginase activity, as indicated in Figs. 1 and 5. Such inhibition may reduce downstream production of key products such as polyamines, proline, or glutamate, an hypothesis which has yet to be tested. It should be borne in mind that these tantalizing findings were obtained in studies of cells cultured in supraphysiological concentrations of arginine. Thus, the nature and consequences of the balance between

Figure 5 Potential relationships between NOS and arginases in cytosol and mitochondria. Shaded circles represent mitochondrial transmembrane transporters. NOS and arginase activities in specific cell types *in vivo* remain to be elucidated.

The challenge in comprehending the metabolic consequences of the changing balance in iNOS and arginase expression can be appreciated from the complex stimulus–response profile of NO synthesis and arginase expression in just one cell type—the RAW 264.7 murine macrophage cell line (Table II). Untreated RAW 264.7 cells express a low level of type II arginase but no type I arginase or iNOS. Arginase expression is induced under some but not all conditions in which iNOS also is induced, but the arginase isoforms are not coordinately regulated. As suggested above, these differences in expression of the arginase isozymes are likely significant because of the distinct subcellular localization of the isozymes. For example, the mitochondrial type II arginase may be less susceptible to inhibition in NO-producing cells than is the cytosolic type I arginase, depending on how readily *N*^G-hydroxyarginine traverses the

mitochondrial membrane. In any case, it is clear from Table II that the arginases are more promiscuously induced in this macrophage cell line than is iNOS, raising the intriguing possibility of similarly complex stimulus–response profiles in other NO-expressing cell types. The physiological consequences of these complex patterns of expression are just beginning to be explored. The development of highly potent arginase inhibitors (though none are isoform-specific) and our development of a viable knockout mouse model lacking type II arginase expression should greatly aid in these studies.

Arginine Transport

This section will only highlight selected features of arginine transport because this topic is developed more fully in Chapter 14 by Mann and Closs. A large fraction of cellular arginine requirements are met by uptake of extracellular arginine via one or more specific transporters, including systems y⁺, b^{0,+}, B^{0,+}, and y⁺L. As noted above, about half of the arginine used for whole-body NO synthesis in healthy adult humans is derived from the plasma. Thus, arginine transport systems represent a major control point for regulating availability of arginine for NO synthesis. This notion is further supported by the fact that the apparent *K_m* of NO-producing cells for extracellular arginine is about the same as the *K_m* of the arginine transport systems. A mitochondrial arginine transport system exists, indicated schematically in Fig. 5, but has not been well characterized.

Although the expression of the different transport systems varies among different cell types, the most important system for arginine uptake in many NO-producing cells is system y⁺, which transports lysine and ornithine in addition to arginine. The *K_m* of system y⁺ for arginine is near the normal plasma concentration of this amino acid. Thus, this transport system is probably not saturated *in vivo* but may become saturated at the high arginine concentrations commonly found in tissue culture media.

Uptake of arginine can be competitively inhibited by lysine and ornithine, as well as by some positively charged NOS inhibitors such as *N*^G-monomethyl-L-arginine and *N*^G-iminoethyl-L-ornithine. As a result, these NOS inhibitors will not only reduce cellular NO synthesis by directly inhibiting NOS but also can reduce arginine availability by limiting its uptake. On the other hand, NOS inhibitors such as aminoguanidine, *N*^G-nitro-L-arginine, and *N*^G-nitro-L-arginine methyl ester do not compete with arginine for uptake by system y⁺.

System y⁺ is commonly induced by the same inflammatory stimuli which induce iNOS. In fact, induced NO synthesis in some cell types has a strict requirement for coinduction of system y⁺. Thus, induction of both the arginine transport system and argininosuccinate synthase serves to maximize availability of arginine for NO synthesis in activated cells. The need to maximize arginine availability is somewhat surprising because the *K_m* values of the NOS isozymes for arginine are in the 2–20 μ*M*, suggesting that these enzymes

would almost always be saturated with substrate in intact cells. In fact, rates of cellular NO synthesis can be varied according to extracellular arginine concentration, a phenomenon known as the arginine paradox. This suggests that measurements of intracellular arginine concentrations are highly inaccurate, that the K_m of the NOS isozymes inside cells is quite different than the K_m value determined with cell extracts or purified enzymes, or that multiple intracellular pools of arginine exist. Current evidence suggests that the last possibility may be most likely. For example, eNOS and the arginine transporter appear to be colocalized in plasma membrane caveolae, suggesting that, as arginine is taken up, it does not rapidly mix with the total intracellular arginine pool but is preferentially delivered to eNOS. This is analogous to the proposition that arginine may be preferentially delivered or channeled to iNOS in the citrulline–NO cycle.

Agmatine

Agmatine [4-(aminobutyl)guanidine], the decarboxylation product of arginine (Fig. 1), was discovered to be produced by mammalian cells only as recently as 1994. Although it can bind to α_2 -adrenergic and imidazoline receptors, suggesting that it may represent a novel neurotransmitter, it also has potential for regulating NO production. Owing to its guanidino group (Fig. 2), it is a weak competitive inhibitor of NOS (Fig. 1), yet paradoxically it can stimulate cNOS activity in intact cells. The latter effect occurs at physiological levels of agmatine, probably via stimulation of intracellular calcium flux, whereas direct inhibition of NOS occurs at higher concentrations (K_i of 0.2–7.5 mM, depending on the NOS isoform). It is unlikely that endogenously produced agmatine acts as a NOS inhibitor *in vivo* because the concentrations required for inhibition are much higher than the low concentrations (approximately 1–10 μM) found in tissue. Moreover, agmatine acts as a feedback inhibitor of arginine decarboxylase, thus limiting its accumulation at the site of synthesis. Its accumulation can be further limited by the action of agmatinase and diamine oxidase (Fig. 1). Net production and accumulation of agmatine by specific cells will, of course, depend on the balance between activities of the synthetic and degradative enzymes, but this information is not yet available for most cell types. Nevertheless, relatively high local concentrations of agmatine can be achieved via its accumulation and release from storage vesicles in neural cells. Even so, it is not clear whether local concentrations become high enough to inhibit NOS activity.

Neither arginine decarboxylase nor agmatinase has been well characterized, though analysis of cell homogenate fractions indicates that both enzymes are localized within mitochondria. Limited information is available concerning the tissue distribution and regulation of arginine decarboxylase and agmatinase. Arginine decarboxylase activity and/or mRNA has been detected in brain, astrocytes, kidney, liver, adrenal gland, and gut. Agmatinase is expressed in brain, liver, and kidney. Both enzymatic activities are present in the RAW 264.7 murine macrophage line in the presence and

absence of stimuli which induce iNOS. As no specific inhibitors for arginine decarboxylase or agmatinase have been identified, however, the impact of these activities on NO synthesis by these or any other cells has not been determined.

A partial cDNA sequence for a putative rat arginine decarboxylase was described in 1995, but no subsequent reports of the complete cDNA sequence or functional characterization of the expressed protein have appeared; its subunit size is unknown. Agmatinase is initially synthesized as a protein of 352 residues, and a short N-terminal fragment is probably removed as part of its transport into mitochondria. Inasmuch as both arginase and agmatinase catalyze the hydrolytic cleavage of a guanidino group from their respective substrates, there is a possibility that N^G -hydroxyarginine may inhibit agmatinase as it does the arginases.

Agmatine levels also may be regulated by diamine oxidase, a copper-containing enzyme which is a member of a family of amine oxidases. Diamine oxidase acts on agmatine to produce guanidinobutylaldehyde, hydrogen peroxide, and ammonia (Fig. 1). The structure of guanidinobutylaldehyde suggests that this compound may be an inhibitor of NOS activity. Mammalian diamine oxidase has been cloned, and two isoforms have been identified. It has a relatively broad substrate specificity, with the ability to catabolize various diamines and histamine as well as agmatine. Its contribution to agmatine catabolism is unknown.

Summary

1. Endogenous protein degradation and diet are major contributors to the free arginine pool *in vivo*. The arginine transport systems and the arginases play key roles in regulating the concentration and delivery of this pool of arginine to the NOS enzymes.

2. Argininosuccinate synthase, the arginases, and the arginine transporters are critical regulators of intracellular arginine availability for NO synthesis. However, little quantitative information currently exists regarding their precise contributions to the control of NO synthesis rates in specific cell types. Their expression can vary dramatically from one cell type to another and also can be regulated over a wide dynamic range in many cells by the same stimuli that regulate changes in NO synthesis and iNOS expression. Overall, these properties indicate that these proteins represent potential targets for development of drugs or gene therapy agents to modulate NO synthesis.

3. Endogenously synthesized agmatine is a potential regulator of NO synthesis *in vivo*, but insufficient information is available to evaluate this possibility.

Relationship between Arginase Activity and Nitric Oxide Production

Masataka Mori and Tomomi Gotoh

Department of Molecular Genetics, Kumamoto University School of Medicine, Kumamoto, Japan

NITRIC OXIDE (NO) IS SYNTHESIZED FROM ARGININE BY NO SYNTHASE (NOS), AND THE AVAILABILITY OF ARGININE IS ONE OF THE RATE-LIMITING FACTORS IN CELLULAR NO PRODUCTION. ARGINASE CATALYZES THE HYDROLYSIS OF ARGININE TO UREA AND ORNITHINE. THUS, BOTH NOS AND ARGINASE USE ARGININE AS A COMMON SUBSTRATE. ARGINASE EXISTS IN TWO KNOWN ISOFORMS, HEPATIC CYTOSOLIC TYPE (ARGINASE I) AND NONHEPATIC MITOCHONDRIAL TYPE (ARGINASE II). SEVERAL LINES OF EVIDENCE HAVE INDICATED THAT ARGINASE COMPETES WITH NOS FOR THE SUBSTRATE AND DOWNREGULATES NO PRODUCTION. INDUCIBLE NOS (iNOS) AND ARGINASE ACTIVITIES ARE REGULATED RECIPROCALLY IN MACROPHAGES BY CYTOKINES, AND THIS MAY GUARANTEE THE EFFICIENT PRODUCTION OF NO. WHEN RAT PERITONEAL MACROPHAGES ARE STIMULATED WITH BACTERIAL LIPOPOLYSACCHARIDE (LPS), iNOS IS INDUCED FIRST, FOLLOWED BY ARGINASE I, SUGGESTING THAT ARGINASE I PREVENTS SUSTAINED OVERPRODUCTION OF NO. DIFFERENT TIME COURSES OF iNOS AND ARGINASE I INDUCTION ARE ALSO OBSERVED *IN VIVO* IN RAT TISSUES. ON THE OTHER HAND, ONLY ARGINASE II IS INDUCED IN ACTIVATED MOUSE MACROPHAGE-LIKE RAW 264.7 CELLS, AND BOTH ARGINASE FORMS ARE INDUCED IN PRIMARY CULTURES OF MOUSE MACROPHAGES. NO PRODUCTION IN ACTIVATED MACROPHAGES IS ENHANCED BY THE ARGINASE INHIBITORS *N*^ω-HYDROXY-D,L-INDOSPICINE AND L-NORVALINE. IN LPS-ACTIVATED MACROPHAGES AND ENDOTHELIAL CELLS, *N*^G-HYDROXY-L-ARGININE (NOHA), AN INTERMEDIATE OF THE NOS REACTION, ACCUMULATES AND INHIBITS ARGINASE ACTIVITY, WHICH MAY BE A MECHANISM TO ENSURE SUFFICIENT ARGININE AVAILABILITY FOR HIGH-OUTPUT PRODUCTION OF NO. IN IMMUNOSTIMULATED RAW 264.7 CELLS, NO PRODUCTION IS ELEVATED, AND NO-MEDIATED APOPTOSIS FOLLOWS. WHEN ARGINASE II IS INDUCED, NO PRODUCTION IS MUCH DECREASED, AND THE CELLS ARE RESCUED FROM APOPTOSIS. NO-MEDIATED APOPTOSIS CAN ALSO BE PREVENTED BY TRANSFECTION WITH EITHER AN ARGINASE I OR AN ARGINASE II EXPRESSION PLASMID. ALL THESE RESULTS INDICATE THAT NO PRODUCTION IS MODULATED BY ARGINASE ISOFORMS AT THE LEVEL OF BOTH ACTIVITY AND ENZYME AMOUNT IN VARIOUS CELL TYPES.

Metabolism of Arginine and NO

Arginine is a precursor for synthesis of urea, polyamines, creatine phosphate, agmatine, nitric oxide (NO), and proteins (Fig. 1). Arginine is synthesized from citrulline by the successive actions of argininosuccinate synthetase (AS) and argininosuccinate lyase (AL), the third and fourth enzymes of the urea cycle (ornithine cycle). The major site of arginine synthesis in ureotelic animals is the liver, where arginine generated in the urea cycle is rapidly converted to urea and ornithine by arginase with no net synthesis of arginine occurring. Another major site is the kidney, where arginine is synthesized from citrulline and is released into the blood circulation. However, many other tissues and cell types also contain low levels of AS and AL. In adult animals, citrulline is produced primarily in the small intestine from NH_3 , CO_2 , and ornithine by carbamylphosphate synthetase I (CPS I) and ornithine transcarbamylase (OTC), the first two enzymes of the urea cycle, and is supplied to the kidney and probably to other tissues for synthesis of arginine. Citrulline is also formed from arginine as a coproduct of the NOS reaction, forming a cycle which is called the citrulline–NO cycle. On the other hand, arginine is hydrolyzed to urea and ornithine by arginase. Thus, arginase and NOS use arginine as a common substrate. Evidence is accumulating to show that arginase competes with NOS for arginine and downregulates NO production by decreasing intracellular arginine. Arginine metabolism was reviewed by Wu and Morris (1998).

Arginase I

Arginase exists in two isoforms, liver-type arginase I and nonhepatic-type arginase II. Arginase I has been purified from a number of sources, including rat (Schimke, 1964; Hirsch-Kolb and Greenberg, 1968; Tarrab *et al.*, 1974),

mouse (Spolarics and Bond, 1988), and human (Beruter *et al.*, 1978; Brusdeilins *et al.*, 1985), and the crystal structure of the trimeric rat enzyme was revealed (Kanyo *et al.*, 1996). cDNAs for the rat (Kawamoto *et al.*, 1987) and human enzyme (Haraguchi *et al.*, 1987) were isolated, with the predicted polypeptides being composed of 323 and 322 amino acid residues, respectively. Human arginase I was expressed in *Escherichia coli* and was purified (Ikemoto *et al.*, 1990).

The Arginase I Gene

The human arginase I gene was mapped to chromosome 6q23 (Sparkes *et al.*, 1986). The genes from rat (Ohtake *et al.*, 1988) and human (Takiguchi *et al.*, 1988) are about 12 and 11.5 kb long, respectively, and consist of 8 exons (Fig. 2). The 5' region of the rat gene from -193 to $+286$ bp exhibited a moderately liver-selective promoter activity in an *in vitro* transcription analysis using nuclear extracts of rat liver and brain (Takiguchi and Mori, 1991). Deletion analysis of the rat arginase I promoter region in hepatoma cell lines showed multiple negative regulatory elements between positions -1500 and -299 bp, and multiple positive elements between -299 and -52 bp (Gotoh *et al.*, 1994). There are two binding sites for CCAAT/enhancer binding protein (C/EBP), one at a position around -90 bp and the other around -55 bp. Binding of C/EBP family members to the region around -55 bp stimulates promoter activity (Chowdhury *et al.*, 1996). Hepatocyte nuclear factor-4 (HNF-4) represses the promoter activity without directly binding the promoter region, and the region overlapping with the C/EBP-binding site at around -55 bp is responsible for the HNF-4 repression (Chowdhury *et al.*, 1996).

Transcription of the rat arginase I gene is induced by glucocorticoids in a delayed secondary manner. A glucocorticoid-responsive and hepatoma cell-selective enhancer is

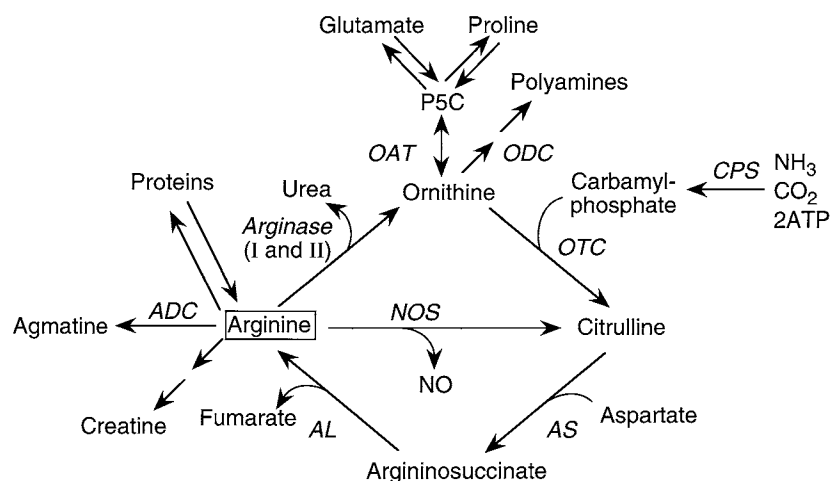

Figure 1 Arginine metabolism. The urea cycle is composed of carbamylphosphate synthetase I (CPS), ornithine transcarbamylase (OTC), argininosuccinate synthetase (AS), argininosuccinate lyase (AL), and arginase I. The citrulline–NO cycle is composed of nitric oxide synthase (NOS), AS, and AL. OAT, ornithine aminotransferase; ODC, ornithine decarboxylase; ADC, arginine decarboxylase; P5C, pyrroline-5-carboxylate.

Figure 2 Schematic representation of the rat arginase I gene and binding factors to the promoter and enhancer regions. The transcription start site is indicated by the hooked arrow. The enhancer is located 11 kb downstream from the start site of the gene.

located 11 kb downstream of the promoter and around intron 7 (Gotoh *et al.*, 1994). In this enhancer region, there are four protein binding sites; two of the sites are recognized by C/EBP family members, and the other two bind with unknown factors. Induction of arginase I mRNA by glucocorticoid was preceded by augmentation of the C/EBP β mRNA (Matsuno *et al.*, 1996; Gotoh *et al.*, 1997a). These results are consistent with the notion that the glucocorticoid response of the arginase I gene is mediated by C/EBP β . In C/EBP α -deficient mice, mRNA and protein levels for arginase I and other urea cycle enzymes decrease markedly, and hyperammonemia is evident (Kimura *et al.*, 1998). Regulation of the arginase I gene along with other urea cycle enzyme genes was reviewed (Takiguchi and Mori, 1995).

Arginase II

Besides liver-type arginase I, an isozyme (arginase II) is present in some nonhepatic tissues. Distribution of arginase II mRNA along with arginase I mRNA in normal rat tissues is shown in Fig. 3 (Ozaki *et al.*, 1999). Arginase II mRNA is most abundant in the gut and kidney, and it is present at very low levels in some other tissues. In the gut, the mRNA was most abundant in the jejunum, followed by the ileum, duodenum, and colon, but was barely detectable in the stomach. The tissue distribution of arginase II activity (Herzfeld and Raper, 1976) and protein (Ozaki *et al.*, 1999) is similar to that of mRNA. In the small intestine, arginase II is colocalized with ornithine aminotransferase in absorptive epithelial cells (Ozaki *et al.*, 1999). In the kidney, the enzyme is located in the outer stripes of the outer medulla, presumably in the proximal straight tubules (Miyanaka *et al.*, 1998). The localization of arginase II in the kidney differs from those of AS and AL, the last two enzymes of arginine biosynthesis, which are localized in the proximal tubules in the cortex. Arginase II in the small intestine and kidney may supply ornithine for the synthesis of polyamines and proline. This enzyme is also abundant in lactating mammary gland and is thought to be involved in proline synthesis (Yip and Knox, 1972).

cDNAs for human (Gotoh *et al.*, 1996; Vockley *et al.*, 1996; Morris *et al.*, 1997), rat (Iyer *et al.*, 1998), and mouse

enzyme (Iyer *et al.*, 1998) have been isolated. The predicted sequence of the human arginase II precursor is shown along with that of human arginase I in Fig. 4. A polypeptide of 354 amino acid residues, including the putative NH₂-terminal presequence for mitochondrial targeting and import, is predicted. Arginase I is located in the cytosol, whereas arginase II is located in the mitochondrial matrix (Spector *et al.*, 1994). It is 59% identical with arginase I. The arginase II precursor synthesized *in vitro* can be imported into isolated mitochondria and proteolytically processed (Gotoh *et al.*, 1996). Comparative properties of arginases have been summarized (Jenkinson *et al.*, 1996).

The human arginase II gene was mapped to chromosome 14q24.1–24.3 (Gotoh *et al.*, 1997b). The mouse gene was isolated (Shi *et al.*, 1998). It contains 8 exons like the arginase I gene, and the identity of the exon–intron boundaries among the two isoform genes is consistent with a gene duplication. The sequence of the promoter region of the mouse gene was presented.

Figure 3 Distribution of arginase I and II mRNAs in normal rat tissues. Total RNAs (10 μ g) from rat tissues were electrophoresed in formaldehyde-containing 1% agarose gels and transferred to nylon membranes. The filters were hybridized using digoxigenin-labeled antisense RNAs for arginase (AI) or arginase II (AII) as probes. From Ozaki *et al.* (1999).

Figure 4 Predicted amino acid sequence of human arginase II precursor (AII) (Gotoh *et al.*, 1996) and comparison with that of human arginase I (AI) (Haraguchi *et al.*, 1987). Identical amino acids are shown by stars, and the triangle shows the putative cleavage site.

Regulation of the Genes for iNOS and Arginase Isoforms in Macrophages

The macrophage is a phagocytic cell of the myeloid lineage found in all organs and connective tissues, and it plays an important part in nonspecific immune reactions. When macrophages are immunostimulated, iNOS is induced and a large amount of NO is produced. Arginine was found to be completely depleted from cell-free supernatants of mixed leukocyte cultures suppressed by the addition of excess mouse peritoneal macrophages (Kung *et al.*, 1977). A marked increase in arginase activity was found in macrophages that had been cultured *in vitro* for 24 hours and in peritoneal cells activated by prior injection of thioglycollate. In contrast, Currie (1978) reported that thioglycollate-induced mouse peritoneal macrophages do not contain detectable arginase activity unless exposed to lipopolysaccharide (LPS) or incubated for 3 days. He showed that activation of macrophages by zymosan or LPS induces the production and release of arginase and kills tumor cells as a consequence of arginine deprivation. However, release of arginase from activated macrophages has not been confirmed.

Albina *et al.* (1988) investigated arginine metabolism in wounds in the rat and found decreased arginine and elevated ornithine contents and high arginase activity. Wound and peritoneal macrophages were shown to convert arginine not only to ornithine (arginase activity) but also to citrulline (arginine deiminase activity was first suggested, but represents NOS activity). Granger *et al.* (1990) analyzed the metabolic fate of arginine in LPS-activated mouse peritoneal macrophages and showed that one-third of arginine is metabolized to NO and citrulline by iNOS and two-thirds is metabolized to urea and ornithine by arginase. Albina *et al.* (1990) examined temporal expression of the two pathways in an ex-

perimental wound model and showed that the NO pathway predominates during the early period, whereas the arginase pathway predominates in a later stage. Modolell *et al.* (1995) tested the induction of arginase in mouse bone marrow-derived macrophages and found that NOS and arginase activities are regulated reciprocally by Th1 and Th2 cytokines. Shearer *et al.* (1997) also observed reciprocal changes in the activities of NOS and arginase when adherent mouse peritoneal exudate cells were treated with mediators of leukocyte activation and inhibition, namely, LPS, γ -interferon (IFN- γ), transforming growth factor β (TGF- β), and corticosterone. In rat alveolar macrophages, Hey *et al.* (1995) reported that 3.8 and 4.6% of added [3 H]arginine (about 20 nM) were utilized by NOS ([3 H]citrulline formation) and arginase ([3 H]ornithine formation), respectively. When the cells were activated with LPS, the formation of [3 H]citrulline was increased about 30-fold, and this was accompanied by a reduction in [3 H]ornithine formation of about 50%.

Wang *et al.* (1995) investigated coinduction of iNOS and arginase using LPS-activated mouse macrophage-like RAW 264.7 cells and immunoprecipitation experiments, and they showed that arginase II is induced. They also showed that the inhibitor of NF- κ B activation, pyrrolidine dithiocarbamate, inhibits the induction of iNOS but not arginase II, and that IFN- γ causes iNOS induction and abolishes arginase II induction. We isolated arginase II cDNA and showed that arginase II mRNA is coinduced with iNOS mRNA in RAW 264.7 cells by LPS, and that this induction of arginase II mRNA is enhanced by dexamethasone and dibutyryl-cAMP, and is prevented by IFN- γ (Gotoh *et al.*, 1996). Surprisingly, however, we found that arginase I, not arginase II, is coinduced with iNOS in rat peritoneal macrophages (Sonoki *et al.*, 1997) (Fig. 5). Coinduction of arginase I and iNOS by LPS was also observed *in vivo* in rat lung (Fig. 6) and spleen. It is of note that, both *in vitro* and *in vivo*, iNOS is induced

Figure 5 Time course of induction of (a) iNOS and (b) arginase I (AI) mRNAs in LPS-treated rat peritoneal macrophages. The cells were treated with 10 μ g/ml of LPS for the indicated times, and total RNAs (0.5 μ g) were subjected to blot analysis. The results were quantified and are represented by means \pm SD. Maximal values are set at 100. Modified from Sonoki *et al.* (1997).

rapidly after LPS treatment, whereas arginase I is induced much later. Induction of arginase I is mediated at least partly by the preceding induction of C/EBP β , a transactivator of the arginase I gene (Sonoki *et al.*, 1997; Gotoh *et al.*, 1997a).

Louis *et al.* (1998) performed experiments to identify arginase isoforms expressed in primary and transformed rodent macrophages. They showed that arginase I is induced in primary cultures of rat and mouse peritoneal macrophages by LPS and that arginase II is induced in mouse, but not rat, peritoneal macrophages in RAW 264.7 cells after LPS treat-

ment; neither J774A.1 nor P388D1 cells contain arginase mRNA. They also found that arginase I is increased in rat wound-derived and mouse peritoneal macrophages by hypoxic or anoxic culture, whereas arginase II is suppressed by O₂ deprivation. They further studied the effect of interleukin-4 (IL-4), a Th2 cytokine which had been shown to increase arginase activity in concert with serum; IL-4 increases arginase I, but not arginase II, mRNA in mouse peritoneal macrophages.

Morris *et al.* (1998) analyzed expression of iNOS and arginase isoforms in RAW 264.7 cells in detail and showed that one or both arginase isoforms may be induced and that arginase expression is regulated independently of iNOS expression. For example, 8-bromo-cAMP strongly induced both arginase I and II mRNAs but not iNOS. Whereas IFN- γ induced iNOS but not arginase, 8-bromo-cAMP and IFN- γ mutually antagonized induction of iNOS and arginase I mRNAs. Dexamethasone, which did not induce either arginase or iNOS, almost completely abolished induction of arginase I mRNA by 8-bromo-cAMP but enhanced induction of arginase II mRNA. LPS induced arginase II mRNA, but 8-bromo-cAMP plus LPS resulted in synergistic induction of both arginase I and II mRNAs. All these results show that the genes for iNOS, arginase I, and arginase II are regulated differentially by LPS and cytokines, and that the arginase isoforms may play distinct, although partially overlapping, functional roles in macrophage arginine metabolism.

We have performed a detailed kinetic analysis of the induction of iNOS, arginase isoforms, and related enzymes in mouse tissues and peritoneal macrophages after LPS treatment (Salimuddin *et al.*, 1999). Both arginase I and II as well as iNOS were induced in peritoneal macrophages; arginase II was induced early, whereas arginase I was induced much later. Similar results were obtained in the lung of LPS-treated mice (Fig. 7). NOS activity was rapidly induced after LPS treatment, reached a maximum at 12 hours, and decreased thereafter. Arginase II activity was present prior to LPS treatment, increased early on and up to 24 hours, and then decreased. In contrast, arginase I activity was not detectable for up to 12 hours and increased at 24 to 36 hours. Arginase II activity was still higher than arginase I activity at 36 hours but arginase I activity may dominate after a while. On the basis of these kinetic studies *in vivo*, we speculate the following events in the endotoxemia. iNOS and arginase II are induced early in activated macrophages. NO produced by the iNOS reaction is cytotoxic to the bacteria. On the other hand, arginase I is induced later than arginase II. Overproduction of NO is toxic to macrophages and neighboring cells. Therefore, there must be a mechanism to prevent sustained overproduction of NO. iNOS activity decreases after early induction *in vivo*, suggesting that NO production decreases in the late stage of endotoxemia. Furthermore, arginase I is induced later and may function in downregulating NO production. The ornithine formed by arginase I and II in endotoxemia may be utilized for synthesis of polyamines and proline (and thus collagen), which are required for cell growth and tissue repair.

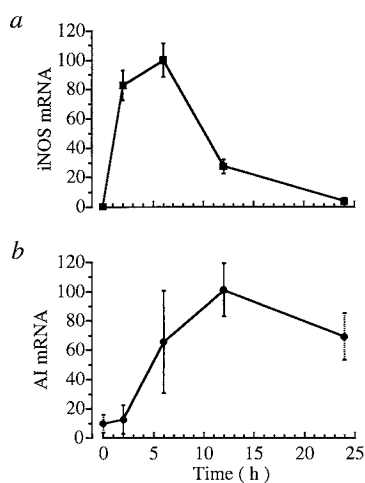

Figure 6 Time course of induction of (a) iNOS and (b) arginase I (AI) mRNAs in the lung after LPS treatment. Total RNA was isolated from the rat lung at the indicated times after LPS injection. Two rats at 0 and 24 hours and three rats at 2, 6, and 12 hours were used. RNAs (1.0 μ g) were subjected to blot analysis. The results were quantified and are represented by means \pm SD (solid bar; $n = 3$) or means \pm range (dotted bar; $n = 2$). Maximal values are set at 100. From Sonoki *et al.* (1997).

Figure 7 Time course of induction of iNOS, arginase I (O), and arginase II (●) activities in the mouse lung after LPS treatment. Mice were injected intraperitoneally with LPS (10 mg/kg body weight). iNOS activity was assayed by measuring conversion of [3 H]arginine to [3 H]citrulline. Arginase I and arginase II activities were calculated by measuring with and without immunodepletion with an antiarginase I antibody. From Salimuddin *et al.* (1999).

To be noted here is that the maximal activity of arginase II (27 nmol/min/mg protein) was about 10,000 times higher than that of iNOS (3.2 pmol/min/mg protein). Assuming that the K_m value of iNOS for arginine is 1–20 μ M (Knowles and Moncada, 1994), this enzyme is expected to be operating at a velocity close to V_{max} at intracellular concentrations of arginine (50–200 μ M). However, when the arginine concentration decreases to lower levels, it becomes one of the rate-limiting factors of iNOS activity. On the other hand, assuming the K_m value of arginase for arginine to be 10 mM (Jenkinson *et al.*, 1996), arginase activity at 50–200 μ M arginine is calculated to be 14–54 pmol/min/mg protein on the basis of simple Michaelis–Menten kinetics. Arginase activity is roughly proportional to physiological concentrations of arginine, and when the intracellular concentration of arginine further decreases, arginase and iNOS activities will become of the same order.

Regulation of NO Production by Arginase in Macrophages

N^G -Hydroxy-L-arginine (NOHA), an intermediate in the biosynthesis of NO, was found to be a uniquely potent competitive inhibitor of arginase I (Daghighi *et al.*, 1994;

Boucher *et al.*, 1994). The K_i value (40–150 μ M) for arginase I is much lower than the K_m value (1–10 mM) for its natural substrate arginine. Since substantial amounts of this intermediate appear to be liberated from the active site of NOS (Klatt *et al.*, 1993; Chenais *et al.*, 1993), it is conceivable that NOHA may act as an endogenous arginase inhibitor in NO-producing cells. In fact, Hecker *et al.* (1995) showed that exogenously applied NOHA strongly inhibited the arginase activity in rabbit or rat alveolar macrophages, and that up to 37 μ M NOHA is released in the medium of rat alveolar macrophages exposed to LPS for 18 hours. Thus, the inhibition of arginase by NOHA during marked iNOS induction may be a mechanism to ensure sufficient availability of arginine for high-output production of NO in activated macrophages.

However, NOHA cannot be used as a pharmacological tool to elucidate interactions between the arginase and NOS pathways, because NOHA itself is a substrate of NOS. Hey *et al.* (1997) addressed this problem by using N^{ω} -hydroxy-D,L-indospicine, another potent inhibitor of arginase, to show that inhibition of arginase by this agent in rabbit alveolar macrophages can cause a shift of arginine metabolism to the NOS pathway. Furthermore, Chang *et al.* (1998) showed that another arginase inhibitor, L-norvaline, enhances NO production from LPS-activated J774A.1 mouse macrophages.

We addressed the same problem using another approach (Gotoh and Mori, 1999). When RAW 264.7 cells were exposed to LPS and IFN- γ , iNOS was induced and NO production was elevated. When dexamethasone and dibutyryl-cAMP were added, both iNOS and arginase II were induced and NO production was much decreased (Fig. 8). This suggests that the induced arginase II downregulates NO production by depleting intracellular arginine. Downregulation of NO production by arginase was demonstrated using NO-mediated apoptosis. When RAW 264.7 cells were treated with LPS and IFN- γ , the cells underwent NO-dependent apoptosis. This apoptosis was prevented when arginase II was induced by further addition of dexamethasone and dibutyryl-cAMP (Fig. 9). Furthermore, when the cells were transfected with arginase II or arginase I expression plasmid, they were rescued from apoptosis. These results indicate that both cytosolic arginase I and mitochondrial arginase II are effective in downregulating NO production and in preventing NO-mediated apoptosis in activated macrophages.

Regulation of NO Production by Arginase in Other Cells and Tissues

Vascular Endothelial Cells

Endothelial cells express high iNOS activity and produce a large amount of NO on stimulation with LPS and cytokines. Buga *et al.* (1996) found that rat aortic endothelial cells contain both arginase isoforms. LPS induces both iNOS and arginase II, but not arginase I. Induction of large

Figure 8 Effect of various reagents on iNOS protein (A), arginase activity (B), and NO $_2^-$ /NO $_3^-$ production (C) in RAW 264.7 cells. The cells were treated with or without 1 μM dexamethasone (Dex) and 1 mM dibutyryl-cAMP for 24 hours and then with LPS (150 $\mu\text{g/ml}$) and IFN- γ (100 U/ml) as indicated at the bottom for 12 hours (A and B) or 18 hours (C). (A) Cell extracts (30 μg protein) were subjected to immunoblot analysis for iNOS protein, and the immunoblots were quantitated and are shown as means \pm SE ($n = 3$). The maximal value is set at 100%. (B) The arginase activity of the cell extracts was measured, and the results are shown as means \pm SE ($n = 3$). (C) NO $_2^-$ plus NO $_3^-$ in the medium was measured and the results are shown as means \pm SE ($n = 3$). From Gotoh and Mori (1999).

amounts of iNOS by LPS and cytokines results in large quantities of NO, citrulline, and NOHA, but urea production is markedly diminished. Decreased urea production is attributed to increased formation of NOHA. Thus, arginase inhibition by NOHA may also ensure an arginine supply for NO production in endothelial cells.

Lung

In the lung, NO plays an important role in pulmonary capillary transport function and associates with inflammation. Among the arginase isoforms, arginase II is the major form present in normal rat and mouse lung (Carraway *et al.*,

Figure 9 Effect of arginase II induction on apoptosis of RAW 264.7 cells. The cells were treated with 1 μM dexamethasone (Dex) and/or 1 mM dibutyryl cAMP for 24 hours, and then treated with LPS (150 $\mu\text{g/ml}$) and IFN- γ (100 U/ml) for 6 hours. DNAs were isolated, resolved on an agarose gel, stained with SYBR Green I, and visualized for DNA fragmentation by UV transillumination. From Gotoh and Mori (1999).

1998; Salimuddin *et al.*, 1999). After LPS administration, iNOS and arginase I are markedly induced in the rat lung (Sonoki *et al.*, 1997), whereas iNOS and both arginase isoforms are induced in the mouse lung (Salimuddin *et al.*, 1999). On the other hand, Carraway *et al.* (1998) reported that iNOS is induced in the lung in sepsis from cecal ligation and puncture in the rat, whereas arginase II becomes almost undetectable. Que *et al.* (1998) examined expression of arginase isoforms in hyperoxic lung injury. They found that both arginase I and II are upregulated after exposure to 100% O $_2$ for 60 hours. Immunostaining showed that increases in arginase I and II occur mainly in the peribronchial and perivascular connective tissues. iNOS was not induced under these conditions. Therefore, the role of arginase in hyperoxic lung may be linked to connective tissue elements rather than regulation of NO production. Schapira *et al.* (1998) studied metabolism of arginine in lung macrophages and neutrophils following intratracheal instillation of silica into rat lungs *in vivo*. The results show that lung inflammatory cells increase arginine uptake and metabolism by both NOS and arginase following *in vivo* silica exposure. Therefore, NOS and arginase appear to compete for arginine in these cells.

Kidney

Arginase II is highly expressed in the proximal straight tubules in the outer medulla and in a subpopulation of the proximal tubules in the cortex (Miyanaka *et al.*, 1998), but its role in the regulation of NO production is not known. NO is thought to be important in regulating blood flow in glomeruli and in glomerulonephritis. Both NOS and arginase activities were found to be present in glomeruli, and arginase activity was increased by more than five-fold in nephritic glomeruli (Jansen *et al.*, 1992). By using an acute glomerulonephritis model in rats, Cook *et al.* (1994) found the highest NOS activity in glomeruli on day 1 and the highest arginase activity on day 4; both declined by day 7. Macrophages were shown to be a major source of glomerular NOS, whereas glomerular mesangial cells appeared to be a major source of arginase. Ketteler *et al.* (1996) also reported that, in antithymocyte serum-induced glomerulonephritis in rats, iNOS gene expression and NO production are increased very early, whereas arginase activity was increased later and until 5 days of disease. In glomerular acute immune complex inflammation, arginase I was induced in nephritic glomeruli, and in mesangial cells stimulated with IL-4 and cAMP, whereas arginase II was constitutively expressed (Waddington *et al.*, 1998a). We found that arginase II is elevated in rat kidney in response to LPS, dibutyl-cAMP, and dexamethasone, but the cell type with the induced enzyme was not identified (Ozaki *et al.*, 1999). To understand regulation of arginase and its relationship to NO production, Waddington *et al.* (1998b) studied effects of NOHA and IL-4 on urea and NO synthesis by glomeruli and mesangial cells during rat immune glomerulonephritis. The results show that arginase is inhibited during high-output NO production and is stimulated with NO suppression. Taking these results together, one can see that the complicated regulation of NOS and arginase isoform genes is important in controlling the balance of inflammatory and repair mechanisms during the course of glomerulonephritis.

Pancreatic β -Cell

A constitutive NOS pathway is thought to negatively control arginine-stimulated insulin release by pancreatic β -cells. Gross *et al.* (1997) investigated the effect of glucose on this mechanism and whether it could be accounted for by NO production. They found that a NOS inhibitor L-NAME strongly potentiates arginine-induced insulin secretion at 5 mM glucose. It was concluded that the potentiation of arginine-induced insulin secretion resulting from the blockade of NOS activity is not due to decreased NO production but is probably accounted for by decreased levels of NOHA or citrulline, resulting in the attenuation of an inhibitory effect on arginase activity.

Induction of NOS and generation of NO in β -cells may mediate cytokine-induced dysfunction, leading to insulin-dependent diabetes mellitus. Cunningham *et al.* (1997) investigated the effect of IL-1 β , NOHA, and NO donors on

arginase activity in the rat insulinoma-derived RINm5F cells. When the cells were treated with IL-1 β , NOS activity was increased and arginase activity was decreased. Arginase was significantly inhibited by NOHA and NO donors. On the basis of these results, they concluded that during cytokine-directed β -cell assault, NOS-catalyzed production of NOHA and NO may inhibit arginase, thereby increasing the availability of arginine for NO production.

Central Nervous System

NO is involved in many physiological and pathological processes in the brain. Possible regulation of NO production by arginase in the brain is of great interest and potentially important. However, little is known about arginase in this tissue. Nakamura *et al.* (1990) reported that arginase I-like immunoreactivity is present rather diffusely throughout the rat brain. On the other hand, RNA blot analysis showed that arginase II is expressed at low levels in various portions of human brain, whereas arginase I expression was barely detectable (Gotoh *et al.*, 1997b). Braissant *et al.* (1999) performed an *in situ* hybridization study of mRNAs for the enzymes of arginine metabolism in rat brain; they showed that neuronal NOS (nNOS) mRNA is restricted to a subpopulation of neurons, whereas arginase II mRNA is present ubiquitously in glial cells and neurons, including the nNOS-positive neurons. Therefore, in the neurons expressing both nNOS and arginase II, arginase II may regulate nNOS-dependent NO production. Further studies on the relationship between the NOS and arginase isoforms under physiological and pathological conditions are awaited.

ALTHOUGH MUCH IS KNOWN REGARDING THE BIOLOGICALLY IMPORTANT CHEMICAL REACTIVITY OF NITRIC OXIDE (NITROGEN MONOXIDE, NO) AND ITS DERIVATIVES, MUCH LESS IS KNOWN REGARDING ITS DYNAMICS *IN VIVO*. SINCE NO IS HIGHLY MOBILE, ITS ACTIONS WILL BE WIDESPREAD, AND THIS MOVEMENT WILL BE CRITICALLY IMPORTANT IN DETERMINING ITS EXTENT OF ACTION. THE SPATIAL MOVEMENT OF NO WILL BE DETERMINED BY ITS PHYSICAL PROPERTIES, SPECIFICALLY, ITS VOLATILITY/SOLUBILITY AND ITS DIFFUSIBILITY. THESE PROPERTIES ARE DISCUSSED HERE AND APPLIED TO THE BIOLOGICAL SITUATION WHERE THERE ARE SPECIFIC SPATIAL ARRANGEMENTS OF SOURCES, SINKS, AND TARGETS FOR NO. THE INCREASED SOLUBILITY OF NO IN HYDROPHOBIC PHASES PREDICTS THAT MEMBRANES ARE IMPORTANT SITES FOR NO REACTIVITY. THE RAPID AND WIDESPREAD DIFFUSIBILITY OF NO PREDICTS THAT IT IS NOT A LOCALLY ACTING MEDIATOR, AND ONE NO-PRODUCING CELL AFFECTS MANY HUNDREDS OF ITS NEIGHBORS. THEORETICAL AND EXPERIMENTAL EVIDENCE SUGGESTS THAT ANY GIVEN NO MOLECULE WHICH REACTS INTRACELLULARLY ENTERS FROM OUTSIDE THE CELL, EVEN IF THE CELL ITSELF SYNTHESIZES NO. THE OVERALL USEFULNESS OF THE CONCEPT OF A "STORAGE FORM" OF NO TO PREVENT ITS RAPID DISAPPEARANCE IS DISCUSSED AND SHOWN TO BE EFFECTIVE ONLY UNDER CERTAIN RESTRICTIVE CONDITIONS. THE EFFECTS OF REACTIONS OF NO WITH HEMOGLOBIN ARE DISCUSSED, INCLUDING HEMOGLOBIN AS AN NO CARRIER. IN LIGHT OF RECENT FINDINGS THAT SHOW THAT ERYTHROCYTE CONSUMPTION OF NO IN THE BLOOD VESSEL IS SUBSTANTIALLY SLOWER THAN EQUIVALENT AMOUNTS OF FREE HEMOGLOBIN, IT IS SUGGESTED THAT THERE IS NO NECESSITY TO POSTULATE AN NO CARRIER TO PRESERVE ITS ACTION AS THE ENDOTHELIUM-DERIVED RELAXING FACTOR.

Introduction

The properties of substances are their characteristic qualities, and these are of two types¹ (Pauling, 1964). Chemical properties are those properties of a substance that relate to

its participation in chemical reactions, where the chemical identity of the substance changes. Physical properties are those properties of a substance that can be observed without changing the substance into other substances. Here I will address the physical properties of nitric oxide (nitrogen monoxide). In addition to paramagnetism [which is not dealt with here but is covered elsewhere (Henry *et al.*, 1993; Wilcox and Smith, 1995; Singel and Lancaster, 1996; Henry and

¹Ligand–receptor binding can be considered a type of chemical reaction, although no new covalent bonds are formed.

Singel, 1996; Kalyanaraman, 1996; Henry *et al.*, 1997)], the two most important physical properties of nitric oxide (NO) in biology are its volatility/solubility and its diffusibility. As we will see, an understanding of these properties of NO are as important to understanding its biological actions as an understanding of its chemical properties.

How Reactions Occur

In order for two molecules to react, they must collide. However, of the billions of chemical reactions, only a handful are rapid enough that the reaction will occur after only a few collisions. Thus, virtually all reactions occur after the two molecules collide in “just the right way.” In the gaseous phase under high vacuum, the distance between molecules is great enough to ensure that molecules will separate rapidly after a collision. In the condensed phase, however (in aqueous solution or tissue), individual molecules are surrounded by a “cage” of solvent (H_2O) molecules. Thus, parts of the “walls” of these two cages must move away from the two solutes (reactants) in order for the two cages to coalesce and collisions to occur.

Once this happens, however, the molecular pair is surrounded by the solvent cage, which means that during the lifetime of the cage (which is 10^{-10} – 10^{-8} s), the reactant molecules are colliding repeatedly. This is termed an “encounter” (Ridd, 1978). If the probability of the reaction is high enough that the reaction will occur most every time there is an encounter, then the rate of the reaction will depend only on how fast the two molecules will form an encounter. This is called the “diffusion limit.” No reaction can occur more rapidly than this limit. This limit is in the range of 10^9 – $10^{10} \text{ M}^{-1} \text{ s}^{-1}$. In this case, the reaction is essentially “zero order” with respect to concentrations of the reactants; all that is needed is that the amounts of reactions approximate their relative reaction stoichiometry in order for complete reaction of the reactants to occur. If the reaction is slower than the diffusion limit, the rate of the reaction will be dependent on concentration because the rate of formation of encounters is determined by the concentrations of the reactants.

The concentration of NO at any spatial location is determined by its physical properties (the phase where the reaction takes place and the position of the location relative to NO sources and sinks). These properties are described below.

Volatility/Solubility of NO

Volatility of NO

If an aqueous solution is equilibrated with a headspace gas composed of pure NO at 1 atm pressure and 25°C the concentration of NO in solution will be approximately 1.9 mM (Shaw and Vosper, 1977). It is a simple matter to calculate that under these conditions greater than 20 times more

NO molecules will exist per unit volume in the gas than in solution, and so NO is regarded as relatively insoluble in aqueous solution (although its solubility is slightly greater than the solubility of O_2). This means that if a solution containing dissolved NO is exposed to a gas interface (headspace) which is not pure NO, the NO in solution will readily volatilize to exist mostly in the headspace, depending on the volume of the headspace compared to the solution volume. This phenomenon has important consequences (which are not always appreciated) for certain experiments where solutions (e.g., containing cells) are injected with small volumes of NO-saturated solutions. In the absence of a gas–liquid interface (such as in *in vivo* compartments except for the lung), unless the concentration approaches 1–2 mM (a highly unlikely condition), NO will exist completely as a dissolved nonelectrolyte. Thus, in virtually all its biological actions NO is not a gas.

Solubility of NO

On a molar basis NO is approximately nine times more soluble in organic solvents than water (Shaw and Vosper, 1977). This means NO will concentrate in hydrophobic phases in tissue (membranes, lipid inclusions, chylomicrons, and lipoprotein complexes). This effect could have several important consequences biologically. First, the hydrophobic nature of NO will mean that the lipid bilayer of membranes will pose no barrier to its movement in tissue (Collander and Barna, 1933; Subczynski *et al.*, 1996). This is one of the most important properties of NO for its biological actions, since this means there is no need for “packaging” of the molecule in order for NO to exert its effects on additional cells, other than the cell that makes it. In addition, the concentration of NO in hydrophobic compartments (i.e., on a per volume basis) will be higher than in the aqueous phase, as has been observed experimentally (Malinski *et al.*, 1993). This could mean that hydrophobic compartments may serve as substantial “reservoirs” for NO. However, in most parenchymal tissue the total volume of the membrane is much less than the total cellular aqueous volume, so the total amount of NO (i.e., total number of moles in each compartment at any one time) will still be much higher in the aqueous than membrane compartment. In addition, the extremely rapid diffusivity of NO [both in the aqueous phase as described below and in the membrane phase (Vanderkooi *et al.*, 1994; Denicola *et al.*, 1996)] means that both depletion of NO (from reaction) and also production in either compartment will occur essentially simultaneously in both compartments.

The increased concentration of NO (and also O_2) within the hydrophobic compartment could increase reaction rates there, meaning that the membrane could become an important site for the reactions of NO [including reactions with lipids (Rubbo *et al.*, 1994)] and for the generation of its products. Another potentially important effect is that because chemical reactions are greatly influenced by the solvent in which the reaction takes place, these and other possible reactions may occur with mechanisms that are dif-

ferent from those of reaction in water. Unfortunately, little is known about the reactions of NO in hydrophobic phases, although the general phenomenon of acceleration of reactions by the presence of hydrophobic phases is well documented (Cordes and Dunlap, 1969; Fendler and Fendler, 1975); this phenomenon has also been considered on a theoretical basis for both small radical molecules in general (Babbs and Steiner, 1990) and NO (Gordin and Nedospasov, 1998). We have studied the reactions of NO with dioxygen in hydrophobic phases (Liu *et al.*, 1998a), as described below.

The reaction of NO with O₂ in aqueous solution (Ford *et al.*, 1993) results in the formation of nitrous acid:

The rate of this reaction is second order in NO concentration and first order in oxygen concentration:

$$\frac{-d[\text{NO}]}{dt} = 4k[\text{NO}]^2[\text{O}_2] \quad (2)$$

This is because although the overall stoichiometry involves 4 moles of NO per mole of O₂, the rate-limiting step is the initial reaction of two NO with one O₂ to produce two NO₂:

Consider the reaction of NO and O₂ taking place in a heterogeneous system (i.e., two different immiscible phases). Assuming the concentration of O₂ is approximately threefold higher in the hydrophobic phase than in the aqueous phase (Subczynski and Hyde, 1983) and that NO is nine times more concentrated in the membrane (Shaw and Vosper, 1977), as depicted in Fig. 1, it can be shown that the rate of autoxidation in the membrane will be nearly 250 times faster than in the aqueous phase, solely because of the concentration effects of the reactants. It is important to appreciate that this does not mean that the overall rate of NO autoxidation in the heterogeneous solution will be 250 times faster, because this figure refers to the rate occurring within

Figure 1 Effects of a hydrophobic phase on NO autoxidation.

each of the respective phases, that is, on a per volume basis. Much less of the volume of a cell is the membrane compared to the aqueous compartment [approximately 3% in tissue (Anonymous, 1961)].

Does the greater rate of NO autoxidation in membranes prevail at the whole-cell level? Even though the total volume of the membrane phase in tissue is only 3% of the total volume (the other 97% is aqueous), this factor of 250 would mean that the overall reaction would occur $1 + 250 \times 0.03 = 8.5$ times faster when membranes are present than when they are not. Thus, 7.5/8.5, or 88%, of the total reaction in tissue occurs within membranes (and other hydrophobic phases). To test this we measured NO disappearance using an NO-selective electrode and tested whether addition of phospholipid vesicles accelerates NO disappearance. Figure 2A shows that, indeed, NO disappears much faster when liposomes (40 mg/ml) are present.

According to simple principles of chemical kinetics, the change in NO concentration with time (under conditions where the concentration of O₂ does not change appreciably, which is true here because the concentration of O₂ in

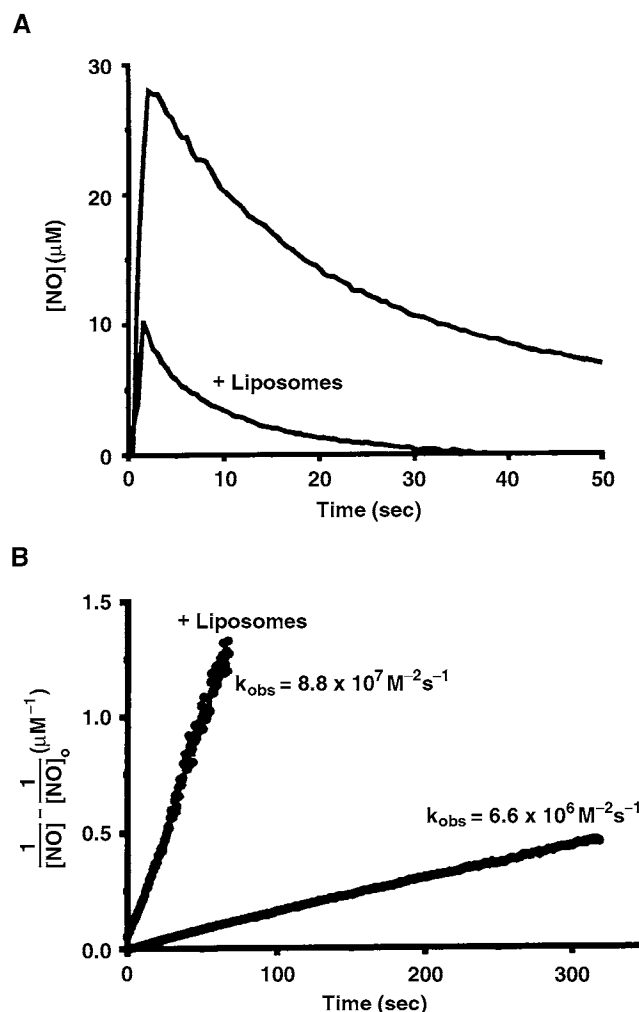

Figure 2 Increased rate of NO autoxidation in the presence of phospholipid vesicles (liposomes).

air-equilibrated buffer is 0.25 mM, much greater than that of NO) is given by the following equation:

$$\frac{1}{[\text{NO}]} - \frac{1}{[\text{NO}]_0} = k[\text{O}_2]t \quad (4)$$

where $[\text{NO}]$ is the NO concentration at time t , $[\text{NO}]_0$ is the NO concentration at zero time, and k is the rate constant. A plot of $1/[\text{NO}] - 1/[\text{NO}]_0$ will thus yield a straight line with slope equal to the rate constant k . From Fig. 2B two things are clear: (1) the rate of the reaction is $88/6.6 = 13.3$ times faster when lipid is present compared to when it is not, and (2) the reaction is still second order with respect to NO concentration (because only a second-order reaction will yield a straight line). The second result strongly suggests that we are still studying NO autoxidation, since this is the only known reaction of NO which is second order in NO concentration (reaction with metals or lipid radicals would be first order).

The real proof that this acceleration of reaction is due to the “sopping up” and thus concentrating of NO (and also of O_2) by membranes came from studies with detergents. These amphiphilic molecules exist as isolated monomers at low concentrations, but at a certain concentration (called the critical micelle concentration, or CMC) micelles form (Fig. 3). Above this concentration, the added detergent molecules incorporate into the micelles instead of dispersing as monomers free in solution, and a distinct hydrophobic phase forms, which increases in volume with increasing detergent added.

Figure 4 shows what happens to the rate of NO reaction with increasing concentrations of three detergents with different CMCs (the CMCs are designated by the arrows). The rate of NO reaction does not change with increasing detergent until the CMC is reached, and above that concentration the rate increases linearly with detergent concentration. Perhaps most importantly, the extent to which each of these detergents increases NO reaction (i.e., the slope of the line as detergent concentration is increased above the CMC) is the same for these detergents. This is true for a variety of detergents and also for isolated cell membranes. This demonstrates that this effect is due solely to the presence of the hydrophobic phase, even for biological membranes.

A complete theoretical analysis reveals that on a per volume basis the rate of reaction of NO with O_2 occurs 300 times faster in the hydrophobic versus aqueous phase. In addition, these calculations reveal that, in tissue, greater than 90% of NO autoxidation occurs within membranes (even with only 3% total tissue volume being membrane volume).

It is important to point out that although the autoxidation reaction of NO will be very slow for physiologically relevant concentrations of NO (generally in the nanomolar range under noninflammatory conditions), there is no doubt that nitrosative reactions take place in tissue (e.g., nitrosothiol formation, as described below). This reaction is generally regarded as the primary mechanism whereby nitrosative chemistry of NO occurs (e.g., DNA base modification and mutagenesis, carcinogenesis), and so these results suggest that the membrane is an important location for these reac-

Figure 3 Formation of micelles from amphipathic molecules.

Figure 4 Effects of micelle formation on NO autoxidation.

tions. In addition, these results highlight the reactions of NO with lipid radical species produced during oxidative stress conditions (Rubbo *et al.*, 1996) and also highlight the antioxidant role for vitamin E, which is generally thought to exert its actions in the membrane milieu (Hogg *et al.*, 1996).

Diffusibility of NO

The rate at which any reaction occurs at a specific location is determined by the concentrations of the reactants at that location. The concentration of NO is governed by the ratio of the rate at which it appears at that location to the rate at which it disappears. Although much effort has been devoted to delineating the rates of synthesis of NO and its reactions, the equally important² process of NO diffusion has

² Actually, NO diffusion is more important because NO synthase is not uniformly distributed at every location in tissue, and so diffusion into any specific location is the more common mechanism of NO appearance there.

received much less attention, and the subject is fraught with misconceptions in the literature.

It is common to see figures such as Fig. 5 when referring to the biological actions of NO. A single cell produces NO, which diffuses to act on a separate cell. However, there are two major inaccuracies in this simple figure: first, NO does not move in a straight line, and, second, NO acts on many more than two cells. As described below, we can be confident in making this assertion because the movement of NO, even in complex media such as tissue, is dictated by the laws of physics.

Movement by Random Diffusion

According to the kinetic theory of gases, the average energy of a gas molecule (\bar{E}) in a collection of molecules is given by

$$\bar{E} = \frac{1}{2} m \bar{v}^2 \quad (5)$$

where m is mass and \bar{v} is the average velocity. The thermodynamic manifestation of the average kinetic energy of a collection of molecules is heat, which is given by

$$\bar{E} = \frac{3}{2} kT \quad (6)$$

where k is the Boltzmann constant and T is the absolute temperature. Combining Eqs. (5) and (6) yields the following relationship:

$$\bar{v} = \left(\frac{3kT}{m} \right)^{1/2} \quad (7)$$

This relationship means that the only quantities which determine the velocity of a molecule (how fast it moves) are the temperature and its mass. In the gas phase in a high vacuum (large distances between molecules), individual gas molecules move in a straight line. In the condensed phase, however, molecules collide much more frequently because of the much greater density. In fact, as described above, solvent (H_2O) molecules form a cage such that movement of solute is dependent on movement (rearrangement) of the solvent molecules in the “wall” so that the solute can “escape.” The result is that the direction in which an NO molecule moves out of the cage is completely random. NO is just as likely to move some arbitrarily defined “forward” direction as it is to move in exactly the opposite “backward” direction. These two probabilities, being of equal magnitude and

opposite sign, cancel each other out, and so the average probability for movement is thus zero.

We know, however, that molecules in solution do move. This is because, although the overall, net probability for a large number of molecules equally (isotropically) distributed throughout the solution³ is zero, each individual molecule experiences thermal variations in the movement of individual molecules surrounding it. This means that a molecule will move in a random walk, each “step” occurring in a random direction depending on where an “opening” appears in the solvent cage surrounding the NO molecule (Lancaster, 1997).

Quantitation of Random Diffusion

The physical quantity which describes the diffusion of a molecule through a solvent is the diffusion constant, D , which is given by Stokes’ law⁴:

$$D = \frac{kT}{4\pi\eta r} \quad (8)$$

where η is the viscosity of the medium and r is the radius of the diffusing molecule. With a value of $\eta = 0.695$ cp (water, 37°C) and $r = 1.4 \times 10^{-10}$ m (for NO), we calculate that $D = 3360 \mu\text{m}^2 \text{s}^{-1}$, which compares remarkably well to the value measured in water [$3300 \mu\text{m}^2 \text{s}^{-1}$ (Malinski *et al.*, 1993)] and also in brain [$3810 \mu\text{m}^2 \text{s}^{-1}$ (Meulemans, 1994)]. The fidelity of these predictions to the results of experimental measurement in tissue (brain) assures us that the fundamental physical laws of diffusion of NO apply to its movement in tissue (as well it should!).

Although the probability for movement in any direction for random diffusion is zero, it is possible to consider the square of the probability (which will be nonzero). In 1905 Einstein proved that the average of the square of the displacement in the x direction $\langle x^2 \rangle$ is defined by the diffusion constant D and the time of movement by the following relationship (called the Einstein–Smolokowski equation):

$$\langle x^2 \rangle = 2Dt \quad (9)$$

For NO ($D = 3300 \mu\text{m}^2 \text{s}^{-1}$), Fig. 6 shows the average distance, $\langle x^2 \rangle^{1/2}$, traveled as a function of time. From this it is clear that NO travels a very considerable distance in a short amount of time. In fact, on average it takes less than 2 ms for an NO molecule to escape from a 5- μm -diameter cell, which means (as described in more detail later) if the NO disappears on reaction within the cell with a rate slower than the 2-ms half-life (corresponding to a first-order rate constant of $3.46 \times 10^2 \text{s}^{-1}$), then the NO is more likely to “escape” the cell than react. This would mean that the actions of NO would be mainly paracrine in nature (as opposed to autocrine). Also, as shown in Fig. 6, NO will diffuse enor-

Figure 5 Depiction of NO diffusion between two cells.

³This will be important when we discuss the nonisotropic (heterogeneous) distribution of a collection of NO molecules.

⁴For diffusion of a molecule with a size similar to the solvent, which is a good approximation for NO in aqueous solution or in tissue/cells.

Figure 6 Root-mean-square distance of diffusion for nitric oxide with increasing times.

mous distances (0.2–0.25 mm) in 5–10 s, which is within the range generally considered to be the half-life of NO.

How many cells will be affected by a single NO-producing cell, with random diffusion away from the producer and different half-lives for the NO? Defining a “sphere of influence” around a single cell (5 μm in diameter), which corresponds to the distance traveled by NO in one half-life (Fig. 7A), Fig. 7B shows the number of 5- μm -diameter cells within this sphere as a function of half-life. For an NO half-life of 5–10 s, this number is 400,000 to 1,000,000. Even with a half-life of 20–200 ms the number of cells affected by a single NO producer is in the hundreds to thousands (Fig. 7B, inset). It seems inescapable, therefore, that for any reasonable NO half-life, NO is not a locally acting mediator but acts at large distances from a single cellular source and thus affects an enormous number of other cells surrounding this one source.

Net Movement of Collections of NO Molecules

Because diffusion is random, we can say that molecules have no “memory”; at any moment in time, a molecule is just as likely to reverse its direction and go “backward” as it is to continue in the direction it has just moved. For example, an NO molecule that has moved halfway from an endothelial cell to a smooth muscle cell is just as likely to turn around and end up back at the endothelial cell as it is to move into the smooth muscle cell. In fact, it makes no difference where this NO molecule was synthesized; the probability of its movement away from that position is identical no matter where it originated. How then can net movement of molecules occur?

Consider two adjacent compartments (A and B), which each contain molecules that diffuse randomly (Fig. 8). The probability for a molecule to cross the boundary from A to B ($P_{A \rightarrow B}$) is determined solely by how many molecules are in compartment A: $P_{A \rightarrow B} = k[\text{NO}]_A$. The converse is true for

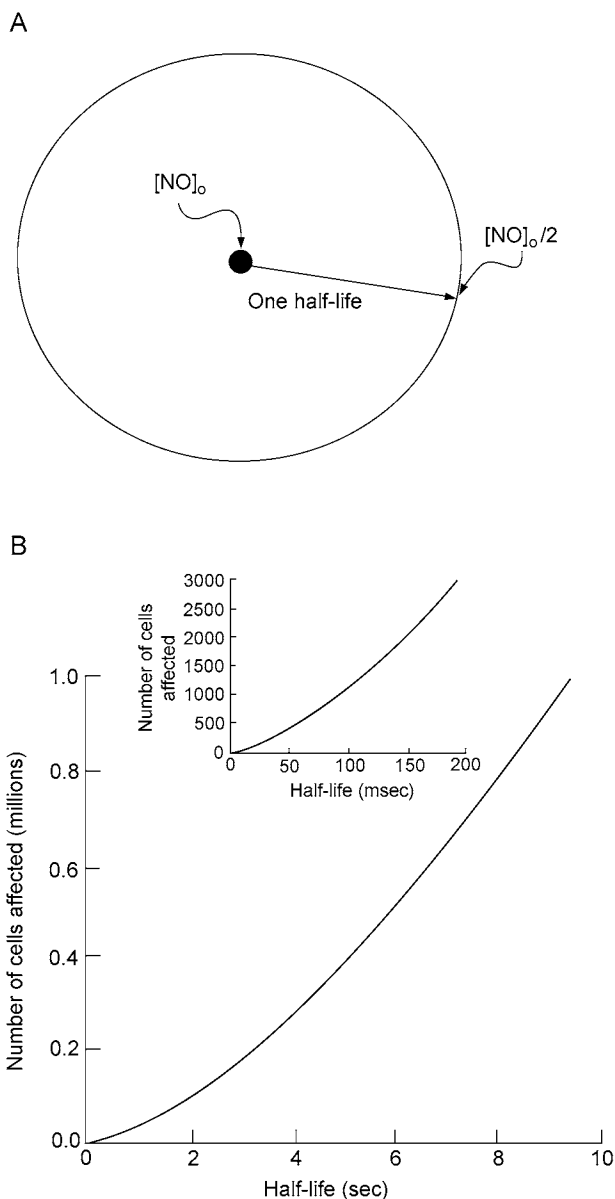

Figure 7 Root-mean-square distance of diffusion for NO with increasing half-life, in terms of numbers of 5- μm -diameter cells within the sphere of influence.

movement from B to A: $P_{B \rightarrow A} = k[\text{NO}]_B$. If the concentrations of NO are the same in both A and B, there will be no net movement because the probabilities are the same; although there is movement of NO across this boundary, no net movement occurs (the molecules simply “change places”). However, if the concentration of NO is less in one compartment than in another, the probability for NO to “escape” this compartment is less than the probability for NO to enter from the adjacent compartment, and so net movement will occur. Thus, although movement of individual molecules has no “direction” in space, net movement of a collection of molecules does occur (in fact, must occur), and the direction of this movement is always from a region of higher to lower concentration.

Probability for NO moving from A to B:
 $k \times [\text{NO}]_a$

Probability for NO moving from B to A:
 $k \times [\text{NO}]_b$

If $[\text{NO}]_a = [\text{NO}]_b$, no net movement
 (NOs will just "change places")

If $[\text{NO}]_a > [\text{NO}]_b$, net movement from A to B

If $[\text{NO}]_b > [\text{NO}]_a$, net movement from B to A

Conclusion: The only thing that "makes"
 molecules move from one place to another
 is the presence of concentration gradients.
 Molecules will always move "downhill."

Figure 8 Probabilities of diffusion between two compartments.

DIFFUSION AWAY FROM A POINT SOURCE

There are two phenomena that will result in disappearance of NO in tissue. One is the existence of chemical reactions that consume NO (sinks), and the other can be characterized as "diffusion into infinity."

Let us consider the formation of NO from a point source, and we will first assume that NO is not degraded. Figure 9 plots the change in concentration of NO at this point source, as NO production is turned on and then off. There are two time regimes, corresponding to regions where the concentration is changing and where the concentration is unchanging. During the initial phase, the NO concentration increases as NO is synthesized. With time, however, the net rate of appearance of NO slows, even though the rate of NO production by the source may remain the same. This is because the rate of diffusion away from the source, at first slow because the concentration of NO at the source is small, becomes more and more significant because the NO concentration at the source is increasing (probability of moving outward increases). Eventually a steady state is reached where the rate

Figure 9 Initiation, steady state, and termination of NO synthesis at a source.

of NO diffusion out of the volume element containing the source becomes equal to the rate of NO production.

If there were spatial boundaries beyond which the NO did not diffuse, the NO would continue to increase with time as long as it is produced (similar to filling a bucket with water). However, with no boundaries (which for all practical purposes applies to NO production *in vivo*) this steady-state constant NO concentration will be maintained as long as the rate of NO production is unchanged. This would be analogous to a fountain in the middle of an infinite parking lot: the height of the fountain is unchanged as long as the water flow is constant, and the water "diffuses into infinity."

At steady state, the concentration of NO will be a maximum at the source, and NO will spread out away from the source, approaching zero concentration at infinite distance. For a given production rate, the width of this "diffusional spread" (Wood and Garthwaite, 1994) will be determined solely by the magnitude of the diffusion constant (assuming no disappearance of NO by reaction). The greater the value for D , the "broader" will be this spread and the lower the concentration will be at the source.

The other factor that will contribute to diffusional spread is the loss of NO due to its disappearance from reaction, which will lower the NO concentration at the location(s) where the reaction takes place. For reaction with O_2 , the simplest assumption would be that this loss is uniform throughout the tissue (due to uniform O_2 distribution, although this is not a completely valid assumption), and so it can be included by specifying a rate expression for NO reaction at all locations.

Figure 10 is a graphical depiction of the diffusional spread of NO away from a point source. At zero time, NO synthesis is initiated at the zero spatial coordinate, and the concentration is monitored at locations $\pm 200 \mu\text{m}$ from the source. NO concentration rises at all locations until approximately 20 s, when a steady state is reached throughout, with NO concentration declining as distance from the source increases. At $t = 40$ s, NO production at the source is terminated, and NO concentration declines and eventually falls to zero, also at every location.

This particular representation is based on a previously published computer simulation (Lancaster, 1994), which was developed to closely match experimental data⁵ for which NO concentration was measured with a microsensor positioned either immediately adjacent to or $100 \mu\text{m}$ distant from a single endothelial cell (Malinski *et al.*, 1993). Thus, at the NO-producing cell the NO concentration increases and

⁵The method (Lancaster, 1994) involves an empirical finite-difference approach wherein the spatial coordinate is subdivided into contiguous compartments, and the rate constants for NO intracompartiment formation/reaction and intercompartment movement are defined. The values of these constants are adjusted until the resulting time and distance profile (on solution of the rate equations using numerical methods with selected initial conditions) match the experimental data published by Malinski *et al.* (1993). The results, which were specifically designed to mimic experimentally measured quantities, are comparable to predictions from analytical solution to Fick's equations.

Figure 10 Representation of the diffusional spread of NO from a source, with initiation, steady state, and termination.

reaches a steady-state value of $1.3 \mu\text{M}$ after 15 to 20 s, with a similar time course $100 \mu\text{m}$ away and a steady-state concentration of $0.83 \mu\text{M}$. The usefulness of this representation is that it allows us to “fill in” the values of NO concentration at all distances within our chosen volume element. From Fig. 10, it is clear that the diffusional spread of NO (as predicted by experimentally measured values) is very large, and it is in fact comparable to that predicted using the Einstein–Smolokowski equation.

OVERLAP OF MULTIPLE SOURCES OF NO

If more than one cell is producing NO in a given tissue volume, the concentration of NO at any location will be the sum of the overlaps of the diffusional spread of NO away from each source. Thus, if the distance between NO-producing cells is large compared to the diffusional spread, the NO concentration will be confined to cells surrounding each of the sources, with no overlap. However, as shown in Figs. 7 and 10, the diffusional spread of NO is very broad, and in order for there to be no appreciable overlap between the profiles of multiple NO-producing cells, there should be less than one cell making NO in a total of more than 1 million. This means that there will always be substantial overlap of NO from multiple sources under virtually any realistic situation.

What would be the difference in NO concentration distribution for a collection of cells producing NO when they are “spread out” versus clustered together? In Fig. 11, five cells are either equally spread out along a quite large distance (0.4 mm) (Fig. 11B) or all clustered together in the center (Fig. 11C), as denoted by the small dots on the distance axis. The profiles reveal that the steady-state concentration is naturally more spread out when the cells are equally spaced as opposed to clustered together, but the difference in NO concentration at any location for the two configurations is actually not major. This is shown specifically in Fig. 11D, which is a plot of the ratio of the steady-state NO concentration as a function of distance for the two situations, which reveals that the difference is a maximum of less than 40%. Thus, for a tissue segment within which multiple NO sources are located, the concentration of NO at any location is relatively

insensitive to exactly where the location is with relation to the sources, and it depends only on how many total NO-producing cells are “in the general neighborhood.”

REACTION VERSUS “ESCAPE” OF NO FROM AN NO-PRODUCING CELL

So far we have been discussing the actions of NO at some location as though they were determined solely by its steady-state concentration at that location. Although this is probably true for many (if not most) of the actions of NO in biology, what about the situation where a target for NO (such as guanylate cyclase) is located immediately adjacent to a source? Independent of the steady-state concentration (apparently), NO molecules released from NOS are more likely to collide with a target immediately next to the NOS than a target farther away.

We have examined this question both experimentally (Stadler *et al.*, 1993; Kim *et al.*, 1994) and theoretically (Lancaster, 1996). This question can be diagrammed as shown in Fig. 12. The question we ask is whether the reaction of NO with its intracellular target is rapid enough that it can occur faster than the NO can “escape” the cell. Using the Einstein–Smolokowski equation we can calculate that the “escape time” for NO from a $5\text{-}\mu\text{m}$ -diameter cell is less than 1 ms. In order to compete with this, the intracellular reaction should occur with a faster rate. Using this as a half-life we calculate that for a second-order reaction (reaction of NO with its target) and an intracellular concentration of the target of 0.1 mM or less, the rate constant must be $\geq 7.3 \times 10^6 \text{ M}^{-1} \text{ s}^{-1}$. This is a quite rapid reaction.

Using isolated rat hepatocytes, we have studied this question experimentally. We have found that coculture of NO-producing hepatocytes with intact erythrocytes (which rapidly consume NO, as described below) results in virtually complete prevention of two intracellular reactions of NO within the hepatocyte, namely, cGMP formation (Kim *et al.*, 1994) and formation of dithioldinitrosyl complexes, as detected by EPR spectroscopy (Stadler *et al.*, 1993). Kinetic modeling reveals that the only way this result can be obtained is if the diffusion of NO out of the cell is more rapid than its reaction within the cell (Lancaster, 1996). In essence,

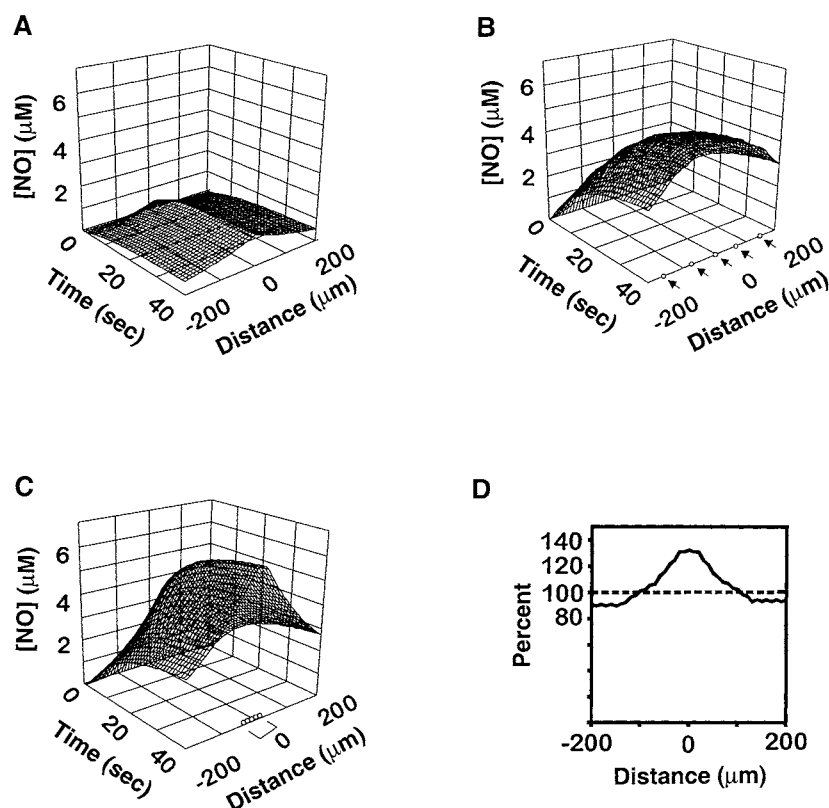

Figure 11 Differences in concentration of NO with five sources, either evenly distributed spatially (B) or clustered together (C).

this means that on average the NO molecule which reacts within a cell (even a cell producing NO) has entered the cell from the outside instead of having just been synthesized there. Thus, although it is most definitely true that a target will respond to NO when it is closer to a source than when it is farther away, this is only because the concentration of NO is higher closer to the source. This means that under these conditions NO is a paracrine effector.

SINKS FOR NO

As described in more detail below, the blood consumes NO rapidly, thus representing a potent sink. For any sink to have an appreciable effect on NO spatial distribution, the

rate of reaction at the location of the sink must be comparable to or exceed the rate of exit by diffusion away from that location. This means that not only must the intrinsic rate constant(s) for the reaction be sufficiently rapid, but the reactant(s) which consume the NO must be present at a concentration that can “keep pace” with the rate of NO diffusion into the location. These reactants thus must either be present in great excess compared to NO or be constantly generated at a rate that is comparable to the NO diffusion. In the case of the erythrocyte, the reaction rate is very fast, and also the reactant (hemoglobin) is present at high concentrations.

The concept of the blood as a sink for NO (Lancaster, 1994), and thus a problem with respect to the postulate that the endothelium-derived relaxing factor (EDRF) is free NO, was not generally appreciated because it was thought that only “half” of the NO produced by the endothelium is scavenged, namely, the “half” that diffuses into the vessel lumen. The “other half,” the NO which moves into the smooth muscle cell, would not be scavenged. However, this is based on the implicit assumption that NO movement is linear and not random, as illustrated in Fig. 13. If movement were linear (Fig. 13, top) the presence of a sink would indeed consume only half the NO, because the NO that started moving a direction away from the sink would continue on in that direction and never be scavenged. However, with random movement (Fig. 13, bottom), at any instant a molecule is just

For 5 μm diameter cell, “escape time” is 0.95 msec.
To complete, for $[\text{target}] \leq 0.1 \text{ mM}$, $k \geq 7.3 \times 10^6 \text{ M}^{-1}\text{s}^{-1}$.

Figure 12 Reaction versus escape of NO from an NO-producing cell.

as likely to completely reverse its direction as it is to continue on in the same direction. In this case, if the sink mechanism is rapid enough, much more than 50% of the NO will be consumed, because any given NO molecule must move into the vessel lumen only once in order to be scavenged. Put another way, only those few molecules whose path never takes them into the vessel lumen escape being scavenged. This will be far less than 50%, owing to the closeness of the endothelium to the vessel lumen. A useful analogy is a large vat of water with a constant source at one end and a leak at the other end. Because the water molecules diffuse rapidly and isotropically, increasing the leak at one end will lower the water level throughout the vat, even immediately adjacent to the water inflow source.

The specific question of hemoglobin scavenging of endothelially produced NO is covered later, but next I discuss the general idea of stabilization of NO by formation of a “bound” form.

“Stabilization” of NO by Binding

Although binding or reaction of NO to form a more stable molecule may seem an attractive mechanism for preventing its scavenging and thus loss of biological actions (Stamler *et al.*, 1992; Vanin, 1991), in fact this process removes NO just as surely as scavenging. In other words, making NO unavailable for reaction with a scavenger (e.g., hemoglobin) also makes it just as unavailable for reaction with its biological target(s) (e.g., guanylate cyclase). It is thus not a straightforward matter to predict the effects of binding or reaction on the biological effects of NO scavenging.

Binding and Free NO Concentration

Synthesis of NO, production of bound form, and disappearance by degradation can be represented as follows:

for which the following expressions hold:

$$\frac{d[\text{NO}]}{dt} = k_3 + k_{-2}[\text{RNO}] - [\text{NO}](k_1 + k_2) \quad (11)$$

$$\frac{d[\text{RNO}]}{dt} = k_2[\text{NO}] - k_{-2}[\text{RNO}] \quad (12)$$

I will first consider the effects of bound NO formation on the steady-state free NO level. Under this condition the rate equations above equal zero, and solution for steady-state NO concentration ($[\text{NO}]_{ss}$) yields

$$[\text{NO}]_{ss} = k_3/k_1 \quad (13)$$

This relationship also holds when no NO binding takes place ($k_2 = 0, k_{-2} = 0$). Thus, the existence of a bound form of NO has no effect on the steady-state NO concentration with ongoing synthesis and disappearance. It can be shown that

Figure 13 Effects of a sink with linear versus random movement.

this will be true with any arrangement of multiple bound forms (not shown).

What are the effects of a bound form on changes in free NO under non-steady-state conditions, that is, when synthesis is initiated and then terminated (Fig. 9)? This can be accomplished by numerical integration of the above rate equations. At zero time, NO formation is initiated, with a rate constant that yields a steady-state concentration of 100 nM. After reaching this steady state, NO synthesis is terminated and NO disappearance is calculated.

Initial calculations revealed that there is no effect of binding on free NO appearance and disappearance under two general conditions, namely, (a) if binding (k_2) is slower than NO disappearance (k_1) or (b) if bound form breakdown (k_{-2}) is slower than formation (k_2). In the first case, NO never has a chance to bind, and in the second, binding takes place but the amount of bound form is small.

Figure 14 presents representative results for all other possible cases ($k_2 \geq k_1$ and $k_{-2} \leq k_2$), where $k_2 = 5k_1$ (Fig. 14A) and $k_2 = 20k_1$ (Fig. 14B). First of all, it is important to point out that, in all cases, at long enough times the steady-state concentration of free NO becomes identical to that when no binding occurs, as predicted above (not shown). The general effect of binding NO is to slow not only the rate of free NO appearance on initiation of synthesis, but also the rate of disappearance on cessation of synthesis. Under conditions where the rate of bound NO breakdown is slower than NO disappearance ($k_{-2} < k_1$, the lower two curves in both plots), the effect is clearly biphasic, with a rapid increase or decrease followed by a slower change.

To summarize, the presence of a bound form of NO will have no effect on the steady-state free NO concentration, only on the rates of change when this steady state is perturbed. Thus, bound form production will not protect free NO against scavenging by blood hemoglobin, a long-term effect.

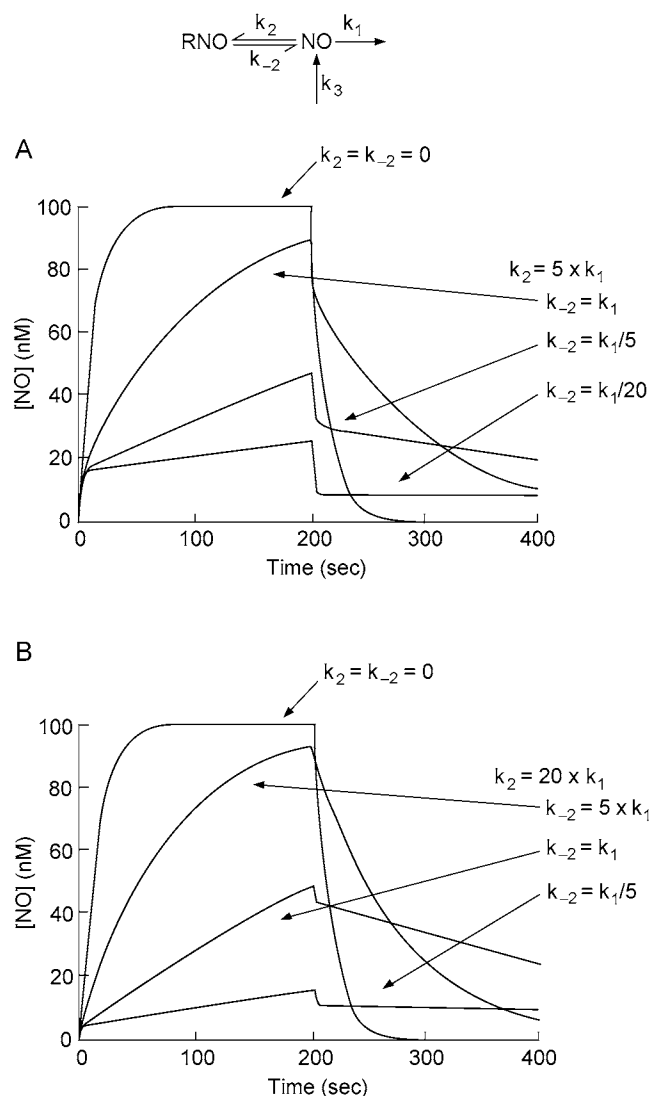

Figure 14 Effects of a “bound” or “storage” form of NO on free NO concentrations with initiation, steady state, and termination of NO production.

Bound NO: Synthesis by NO Synthase and Stimulation of Guanylate Cyclase

It has been suggested that at least one bound form of NO, nitrosothiol, may stimulate guanylate cyclase directly, thus potentially avoiding the inhibition of cGMP production by NO scavengers (Stamler, 1994). Two schemes describe this and other possibilities, specifically, cGMP synthesis stimulated by both bound and free NO, and NO synthase (NOS) production of either free NO [Eq. (14)] or bound NO [Eq. (15)]:

where k_4 is the rate constant for free NO scavenging (hemoglobin) and k_5 is a rate constant for breakdown of RNO not involving NO liberation (the importance of this becomes clear later). Describing cGMP production rate as directly proportional to NO or RNO concentration (either $k_6[\text{NO}]$ or $k_7[\text{RNO}]$) and solution of the rate equations at steady state as previously yield the results presented in Table I.

Several important insights emerge from this analysis. First, if free NO is the product of NOS [Eq. (14)] or if free NO is responsible for guanylate cyclase stimulation [even if the product of NOS is RNO; Eq. (15), right-hand side], then the effect of hemoglobin scavenging (k_4) is the same. As shown in Table I, the terms which contain k_4 (the denominator) are identical for all three cases [denominator = $k_5(k_1 + k_2 + k_4) + k_{-2}(k_1 + k_4)$]. Under conditions where hemoglobin scavenging (k_4) is greater than NO autooxidation (k_1) and also the rate of RNO formation (k_2), the denominators in all three cases simplify to $k_4(k_5 + k_{-2})$. Thus, the rates of cGMP formation will be inversely proportional to the magnitude of k_4 , and thus increasing k_4 will directly decrease cGMP formation.

Second, when the product of NOS is bound NO (RNO) and RNO directly stimulates guanylate cyclase [Eq. (15), left-hand side], then according to Table I (bottom right equation) there are two mathematically possible conditions where large values for k_4 will have no effect on RNO-driven cGMP formation ($k_7[\text{RNO}]$): if $k_5 > k_{-2}$ or if $k_1 > k_2$. If $k_5 > k_{-2}$, then free NO is never formed since RNO disappears via a mechanism not involving NO liberation. If $k_1 > k_2$, then free NO, although formed from RNO breakdown, will disappear before reforming RNO. Thus, although NO is formed, it is only a “by-product,” and so increasing its disappearance by scavenging will have no effect. Importantly, under these conditions, free NO will never have a vasodilatory effect, since it will disappear and never form the active species, RNO.

Thus, to summarize, the only two conditions under which bound NO formation will prevent hemoglobin ablation of NOS-induced cGMP formation are if bound (not free) NO is the immediate stimulant for guanylate cyclase and if either (1) NO is never produced in the path from NOS to guanylate cyclase stimulation or (2) NO is a mere by-product of the path and incapable of vasodilatory actions. Thus, free NO would never be involved.

It is important to point out that for all the situations in Eqs. (14) and (15), reactions are occurring in the same compartment. There is indeed one situation where production of a “bound” form of NO will prevent scavenging, and that is when the bound form moves to an area farther away from a sink and then the NO is liberated. This concept is discussed next in the context of the proposal by Stamler that hemoglobin acts as an NO “carrier.”

Hemoglobin as an NO Sink

Eich *et al.* (1996) have measured the rate of reaction of NO with oxyhemoglobin and oxymyoglobin, and they found that this is an exceptionally rapid reaction, with a rate

Table I Rate Equations for Equations (14) and (15)

NOS makes NO [Eq. (14)]	NOS makes RNO [Eq. (15)]
$k_6[\text{NO}] = \frac{k_6 k_3 (k_5 + k_{-3})}{k_5 (k_1 + k_2 + k_4) + k_{-2} (k_1 + k_4)}$	$k_6[\text{NO}] = \frac{k_6 k_3 k_{-2}}{k_5 (k_1 + k_2 + k_4) + k_{-2} (k_1 + k_4)}$
$k_7[\text{RNO}] = \frac{k_7 k_3 k_2}{k_5 (k_1 + k_2 + k_4) + k_{-2} (k_1 + k_4)}$	$k_7[\text{RNO}] = \frac{k_7 k_3}{k_5 + k_{-2} (k_1 + k_4) / (k_1 + k_2 + k_4)}$

constant of $3.4 \times 10^7 \text{ M}^{-1} \text{ s}^{-1}$. Considering the very high concentration of NO in the blood, this would predict a half-life of NO in the vascular lumen of approximately 2 μs , and would make the blood an unacceptably potent sink for NO produced at its periphery (the endothelium). There are several possible solutions to this problem, beginning with the proposal by Stamler that in fact, rather than being a sink, hemoglobin may be a carrier of NO.

Hemoglobin Nitrosation

Hemoglobin is marvelously designed to transport oxygen to cells in tissue that need it for respiration. Binding of O_2 exhibits cooperativity, which means that binding of one O_2 increases the binding of the next O_2 (hemoglobin can bind a total of four dioxygens). This also means that the loss of an O_2 will increase the loss of the next O_2 . What this means physiologically is that hemoglobin will very efficiently “load up” with oxygen in the lungs, where O_2 concentration is high, and also will “dump” its O_2 in the tissues, where O_2 is less abundant.

In the 1950s and 1960s it became clear that this cooperativity must involve major changes in the fundamental structure of the hemoglobin, when it has oxygen bound compared to when it does not. One of the most important pieces of evidence for this was the finding that a particular cysteine in the β chain changes its reactivity to chemical reagents in the oxy versus deoxy states. In particular, this thiol is more reactive when oxygen is bound to the heme than when it is not (Riggs, 1961; Benesch and Benesch, 1962).

Thiols are targets for modification in cells and tissue in the presence of nitric oxide. Through poorly defined mechanisms, NO can be oxidized and transferred to a nucleophilic acceptor such as a thiol to form nitrosothiols. Jonathan Stamler showed that the reactivity of this thiol in hemoglobin toward nitrosation, like that of other chemical reagents which react with thiols, also is different depending on whether hemoglobin is in the oxy versus deoxy state (Jia *et al.*, 1996; Stamler *et al.*, 1997). Using free hemoglobin in solution, he found evidence for a mechanism involving rapid NO binding to heme followed by nitrosative attack of the Cys- β 93, resulting in nitrosothiol, more rapid than the irreversible consumption of NO through oxidation to produce nitrate (Gow *et al.*, 1999). Thus, rather than consuming NO by irreversible reaction with oxyheme [to form nitrate, as measured by Eich *et al.* (1996)], hemoglobin would become

a nitrogen oxide carrier. In addition, the allosteric nature of NO and oxygen interactions suggest that such a mechanism could result in hemoglobin delivering both oxygen and a vasodilator (NO) simultaneously to tissue.

There are important mechanistic questions that may seem like chemical “details” but which must be answered, including the identities of the “nitrogen oxides” involved [since chemically speaking the “nitrogen oxide” in the hemoglobin nitrosothiol is not nitric oxide (NO) but its oxidation product nitrosonium (NO^+)]. In addition, it is unclear how the nitrosonium moiety [which does not exist as a distinct entity except under extremely acidic conditions (Williams, 1988)] transfers from the proximal heme position to the thiol, which is located on the back side of the heme group in the hemoglobin molecule (Stamler *et al.*, 1997). Finally, there is very little information on the mechanisms of transfer of nitrogen oxide from the nitrosohemoglobin through the entire path to the smooth muscle cell. Specifically, somehow the nitrosonium on hemoglobin must travel from within the red blood cell, across the red blood cell membrane, through the plasma, across the endothelial cell, enter the smooth muscle cell, and liberate nitric oxide, all within the “dwell time” for hemoglobin (a matter of seconds).

In addition, there is much data indicating that the blood is in fact a sink, rather than a reservoir, for NO. For example, acute hemorrhage increases exhaled NO (Carlin *et al.*, 1997), hemodilution causes NO-mediated vasodilation (Mellander *et al.*, 1997), vasodilation in anemic patients is due to increased NO and resistance to normal is restored on infusion of hemoglobin (Anand *et al.*, 1995), and increased hematocrit augments pulmonary hypoxic vasoconstriction and decreases expired NO in isolated lung (Deem *et al.*, 1998).

There are also studies with isolated hemoglobin that are not consistent with the overall concept. The transnitrosation kinetics of S-nitrosohemoglobin (i.e., transfer of the nitrosonium group between S-nitrosohemoglobin and glutathione) (Patel *et al.*, 1999) and the vasorelaxant properties of S-nitrosohemoglobin (when the effects of changes in oxygen tension alone on vascular tone are considered) (Wolzt *et al.*, 1999) are not particularly sensitive to the oxygenation state of hemoglobin. Also, transfer of the nitrosonium group to glutathione [which is the likely mechanism whereby the nitrosonium group would begin its movement from hemoglobin to the smooth muscle cell (Stamler *et al.*, 1997)] does not appear to be fast enough to accomplish nitrogen oxide trans-

fer to the smooth muscle cell during the transit time of an erythrocyte through the precapillary vasculature (Patel *et al.*, 1999; Wolzt *et al.*, 1999), and if such transfer occurs, it will most likely occur in regions of very low oxygen tension (Patel *et al.*, 1999). In addition, under conditions that stimulate those inside the erythrocyte (relatively high concentrations of reduced glutathione), the predominant pathway for S-nitrosohemoglobin breakdown appears to be nucleophilic attack by thiol, generating mixed disulfides and liberating nitric oxide and nitrous oxide (N_2O), with only minor amounts of S-nitrosohemogluthione being formed (Wolzt *et al.*, 1999).

Perhaps most importantly, reactions with hemoglobin in the test tube may not be physiologically relevant, in light of the finding that the reactions of NO with hemoglobin occur nearly 1000 times slower when the hemoglobin is packaged inside the red blood cell than when it is evenly distributed in solution (Liu *et al.*, 1998b). This raises the possibility that reactions with hemoglobin inside the red blood cell may be fundamentally different than with hemoglobin free in solution. An additional important finding is that the presence of an erythrocyte-free zone in blood may also decrease the consumption of endothelial NO by intravascular erythrocytes (Vaughn *et al.*, 1998; Butler *et al.*, 1998; Liao *et al.*, 1999). These effects may well mean that scavenging of NO by oxy-hemoglobin in the blood is not a major problem *in vivo*. In fact, this may be one reason Nature places hemoglobin inside a circulating cell rather than free in the blood vessel: to slow its reaction with NO. This possibility is dealt with in more detail in the next section.

Finally, the theory needs to be tested under physiologically relevant conditions, meaning, experiments with intact red blood cells or whole blood and measurements of the rate of formation and movement of nitrogen oxide from intracellular hemoglobin all the way to its target, guanylate cyclase in the smooth muscle cell.

Modeling Erythrocyte Consumption of NO

Exactly how potent is the consumption of NO by erythrocytes, and how might it affect the biological actions of free NO as an EDRF? In order to address this question, the model in Fig. 15 was utilized. This simplified kinetic scheme depicts three compartments containing NO, the vessel lumen (NO_L), the endothelial cell layer (NO_E), and the abluminal space (NO_A). NO is synthesized by the endothelium with rate constant k_3 , diffuses between compartments via rate constants k_8 , k_{-8} and k_9 , k_{-9} , disappears with rate constant k_1 in all compartments (corresponding to the half-life of NO in parenchymal tissue), and disappears within the vessel lumen by reaction with intraerythrocytic hemoglobin with constant k_R . In Fig. 15, r_L is the vessel radius, d_E is the thickness of the endothelial layer, and d_A is the abluminal distance away from the endothelium containing the smooth muscle cell. Making the assumption that diffusion is faster than autoxidation (k_8 , k_9 , k_{-8} , $k_{-9} > k_1$), solution of the steady-state rate equations yields the following relation for the con-

Figure 15 Model to predict NO concentration at the smooth muscle cell as a function of vessel radius with erythrocyte consumption of NO.

centration of NO at the smooth muscle cell (i.e., in the abluminal compartment):

$$[NO]_A = \frac{k_3}{k_8} \frac{k_9}{k_{-9}} \frac{k_{-8} + k_R}{k_R} \quad (16)$$

In general, the steady-state concentration of an intermediate is equal to the ratio of the rate of formation to the rate of disappearance. Since the rate of formation of NO is k_3 , then from Eq. (16) the rate of loss of NO from the abluminal compartment (k_L) is equal to the product $k_8 k_{-9} k_R / k_9 (k_{-8} + k_R)$. Assuming an effective permeability coefficient for NO across membranes that is similar to the value we have measured in a single erythrocyte ($P = 5.73 \times 10^{-2} \text{ cm s}^{-1}$),⁶ and expressing k_L in terms of P using cylindrical geometries and the values for distance denoted in Fig. 15, yields

$$k_L + \frac{P}{d_A} \left(\frac{r_L}{r_L + d_E + d_A/2} \right) \left(\frac{SA_R}{SA_R + SA_V} \right) \quad (17)$$

where SA_R is the total erythrocyte surface area per luminal volume and SA_V is the vessel surface area per luminal volume.

The two terms in parentheses represent the two major effects of geometry on NO scavenging by erythrocytes. In this model, the most important sink for NO is the erythrocyte, which consumes NO at a rate determined solely by the rate at which it can enter the cell (Liu *et al.*, 1998b). In blood, this will be a function of only the permeability coefficient P and the total erythrocyte surface area per unit volume. However, plasma NO can “escape” by diffusing out of the vessel and into the endothelial compartment, and this process is

⁶ Consumption of NO is limited by the rate at which NO can enter the erythrocyte (Liu *et al.*, 1998b), so this rate can be expressed in terms of an apparent permeability coefficient, P . Utilizing the rate constant for loss of NO of $7.74 \times 10^{-8} \text{ s}^{-1}$ for one erythrocyte per milliliter (Liu *et al.*, 1998b) and a surface area of $135 \mu\text{m}^2$ per erythrocyte (Evans and Fung, 1972), the value for P becomes $5.73 \times 10^{-2} \text{ cm s}^{-1}$.

also a transmembrane simple diffusion process and thus dictated by a permeability coefficient that should be similar in magnitude to the P for movement across the erythrocyte membrane. The rate of this escape will be determined by the vessel surface area per unit internal volume. Thus, the relative fraction of NO in the plasma that is consumed is given by the ratio $SA_R/(SA_R + SA_V)$. This number is the fraction of total membrane area available for NO diffusion that is erythrocyte membrane.

The other geometrical factor that is manifested in Eq. (17) and will determine the extent of NO scavenging (specifically, the concentration of NO in the abluminal compartment) is the size of the vessel with respect to the size of the surrounding endothelial and abluminal compartments. The larger the vessel, the more NO will be scavenged because the endothelial and abluminal compartments surround a large versus small pool of NO-consuming substance. This is expressed in the first term. Specifically, for larger vessels r_L is greater than d_E or d_A , and so this term approaches unity. As the vessel decreases in size, r_L becomes smaller and this term approaches zero; thus, k_L decreases as vessel size decreases.

As pointed out by Liao and co-workers (Vaughn *et al.*, 1998) and Butler *et al.* (1998), there is a third effect of vessel size on the extent of NO scavenging, which is the Fahraeus effect, whereby streaming of blood through small-diameter vessels results in decreased hematocrit. This phenomenon was incorporated into Eq. (17) using an empirical relationship derived from the data of Lipowski *et al.* (1980), which relates the microvessel hematocrit (H_{micro}) to the systemic hematocrit (H_{systemic}) in the cat mesentery using the equation $H_{\text{micro}} = \alpha H_{\text{systemic}}$ where $\alpha = 1.9 \times 10^{-2} \times r_L + 0.1336$. Assuming a surface area to volume ratio for the erythrocyte (β) of $1.436 \mu\text{m}^{-1}$ (Evans and Fung, 1972), the final equation is thus

$$k_L = \frac{P}{d_A} \left(\frac{r_L}{r_L + d_E + d_A/2} \right) \left(\frac{r_L}{r_L + 2/(\alpha\beta H_{\text{systemic}})} \right) \quad (18)$$

Using this model it is possible, given the systemic hematocrit (H_{systemic}), to predict the extent to which NO will be scavenged by the blood using solely geometrical parameters (d_A , d_E , r_L) and experimentally available data (P , α , and β). Using our experimentally determined value for the apparent permeability coefficient of NO ($P = 5.73 \times 10^{-2} \text{ cm s}^{-1}$, see earlier), a value of $2.5 \mu\text{m}$ for d_E (Evans and Fung, 1972), and a value of $50 \mu\text{m}$ for d_A (which seems a reasonable distance within which is located the smooth muscle cell target), Fig. 16 depicts the value of k_L as a function of vascular luminal diameter.

The rate of NO disappearance at the smooth muscle cell (k_L) is very sensitive to vessel radius. As described above, this is primarily because with larger vessels there is more erythrocyte surface area per volume of blood compared to vessel wall surface area; movement of NO across the former results in consumption, whereas movement across the latter results in vasodilator action. Using these values, the half-life

Figure 16 The effects of vessel radius on the rate of NO disappearance at the smooth muscle cell, using the model in Fig. 15.

of NO at the smooth muscle cell ($t_{1/2} = \ln 2/k_L$) varies from approximately 0.3 to 0.1 s over the size range 10–40 μm , which is the range of the arteriolar vascular bed. Although this modeling must be considered only an approximation, it would appear that the “packaging” of hemoglobin within the erythrocyte will indeed slow NO consumption to a level where there will be substantial amounts of endothelially produced NO that survive reaction with oxyhemoglobin. This suggests that EDRF is indeed free NO and that there is no necessity to postulate “bound forms” of NO for its biological actions, at least in the vasculature under normal (i.e., noninflammatory) conditions.

THE CATIONIC AMINO ACID L-ARGININE, THE SUBSTRATE FOR NITRIC OXIDE SYNTHASES (NOS), IS CONSIDERED A SEMI-ESSENTIAL AMINO ACID IN MOST MAMMALS. CONSEQUENTLY, MAMMALIAN CELLS MUST BE CAPABLE OF EXCHANGING CATIONIC AMINO ACIDS (CAA) WITH THE ENVIRONMENT. THE BILAYER OF THE PLASMA MEMBRANE IS IMPERMEABLE TO POLAR MOLECULES, AND THUS SPECIALIZED CARRIER PROTEINS WITH DISTINCT SUBSTRATE SPECIFICITY TRANSPORT HYDROPHILIC SOLUTES SUCH AS AMINO ACIDS. L-ARGININE SHARES THE SAME TRANSPORT SYSTEMS WITH OTHER CAA AND THEIR ANALOGS. IN ADDITION, SOME CAA TRANSPORT SYSTEMS ALSO INTERACT WITH NEUTRAL AMINO ACIDS (NAA). HENCE, CHANGES IN THE EXPRESSION AND/OR ACTIVITY OF THESE TRANSPORT SYSTEMS WILL AFFECT NOT ONLY TRANSPORT OF L-ARGININE, BUT ALSO TRANSPORT OF OTHER CAA, NAA, AND CAA ANALOGS, INCLUDING SOME NOS INHIBITORS. cDNAs ENCODING SPECIFIC CAA CARRIER PROTEINS HAVE ONLY RECENTLY BEEN CLONED. THE DEDUCED PROTEINS BELONG TO THREE DIFFERENT GENE FAMILIES (SOLUTE CARRIER FAMILIES 3, 6, AND 7) AND MEDIATE TRANSPORT ACTIVITIES RESEMBLING SYSTEMS y^+ , y^+L , $b^{0,+}$, OR $B^{0,+}$ WHEN OVEREXPRESSED IN *XENOPUS LAEVIS* OOCYTES OR IN MAMMALIAN CELLS. SYSTEM y^+ SEEMS TO BE THE MOST WIDELY EXPRESSED TRANSPORT ACTIVITY IN CELLS PRODUCING NITRIC OXIDE (NO), AND HENCE THE CARRIER PROTEINS MEDIATING y^+ ACTIVITY (CATIONIC AMINO ACID TRANSPORTER-1, -2B, AND -3) ARE LIKELY TO PLAY AN IMPORTANT ROLE IN SUPPLYING L-ARGININE FOR NOS. IN THIS CHAPTER WE BRIEFLY REVIEW THE CURRENT KNOWLEDGE OF THE MECHANISMS AND REGULATION OF CAA CARRIER PROTEINS AND DISCUSS THE POTENTIAL INVOLVEMENT OF EACH TRANSPORTER IN SUPPLYING L-ARGININE FOR NO BIOSYNTHESIS.

Introduction

The cationic amino acid L-arginine is the physiological precursor of nitric oxide (NO) synthesized by nitric oxide synthases (NOS). In most mammals, L-arginine is considered a semiessential amino acid, reflecting the fact that *de novo* synthesis of L-arginine does not seem to sustain adequate supply, especially under conditions of high demand such as growth and wound healing (for reviews, see Barbul,

1986; Baron, 1994; Reyes *et al.*, 1994; Jenkinson *et al.*, 1996). L-arginine is involved in the synthesis of proteins, creatine, urea, agmatine, and polyamines, and it modulates the delivery of hormones and the synthesis of pyrimidine bases (Fig. 1; Reyes *et al.*, 1994). L-Arginine can be synthesized from L-ornithine via L-citrulline by enzymes of the urea cycle. L-Ornithine can be produced from L-arginine by the action of arginases, but it can also be synthesized from L-glutamate and L-proline (for review, see Wu and Morris,

1998). L-Arginine synthesized by the liver is metabolized locally and does not contribute significantly to circulating plasma L-arginine levels, which are derived mainly from dietary intake of L-arginine (1–2 g/day) and synthesis of L-citrulline and L-arginine by the small intestine and proximal tubules of the kidney, respectively.

In most other cell types, L-arginine synthesis plays a minor role, and consequently this amino acid needs to be taken up from the extracellular space. The plasma membrane is impermeable to polar molecules such as amino acids, sugars, and nucleosides, and thus specialized carrier proteins exhibiting distinct substrate specificity transport these hydrophilic solutes. The carriers for L-arginine can also transport other cationic amino acids (CAA), such as the essential amino acid L-lysine and the nonproteinogenic amino acid L-ornithine, a substrate for polyamine, L-proline, and L-glutamate biosynthesis (Fig. 1). In addition, some CAA transport systems also interact with neutral amino acids (NAA). The existence of specific transport activities for CAA has been recognized for many years, and these have been designated as “transport systems” to emphasize the concept that a complex of different proteins rather than a single carrier protein may mediate a distinct transport activity. Several cDNAs encoding proteins involved in CAA transport have been cloned (see later). Overexpression of these proteins in *Xenopus laevis* oocytes or mammalian cells leads to an increase in the transport of CAA. In some cases [e.g., cationic amino acid transporter proteins (CATs) and the Na^+ - and Cl^- -dependent carrier ($\text{ATB}^{0,+}$)] the expression of a single protein is sufficient to confer full transport activity, whereas in other cases (e.g., heterodimeric amino acid transporters such as 4F2hc/y⁺LAT, 4F2hc/4F2-lc6, and rBAT/b^{0,+}AT) coexpression of two pro-

teins is required. Interactions between these overexpressed proteins with other, as yet unidentified cellular proteins cannot be excluded. Therefore, the term “transport system” is still used to define a specific transport activity in a given cell membrane, whereas the term “carrier” is used to refer to specific proteins that have been characterized at the molecular level. To date it remains unclear which of the specific transport processes for CAA are directly involved in supplying L-arginine for NO biosynthesis. In this chapter, we critically examine the evidence that specific transport systems and carrier proteins are involved in mediating the influx of CAA in mammalian cells. Although we focus principally on CAA transport processes potentially involved in modulating NO production, we also describe transport processes that might not be directly involved in supplying L-arginine for NOS.

Carrier Systems for Cationic Amino Acids in NO-Producing Cells or Tissues

In most cell types, transport of CAA is energy independent, with facilitated exchange of substrate between extracellular and intracellular compartments modulated by the membrane potential (Fig. 2A; White, 1985; Bogle *et al.*, 1991; Bussolati *et al.*, 1993; Sobrevia *et al.*, 1995, 1996; Zharikov *et al.*, 1997). Only one energy-dependent transport system coupling entry of Na^+ to the influx of CAA has been described (system B^{0,+}, Fig. 2B; Van Winkle *et al.*, 1988).

Na^+ -independent membrane transport of CAA was originally assigned to the classic Na^+ -independent system y⁺

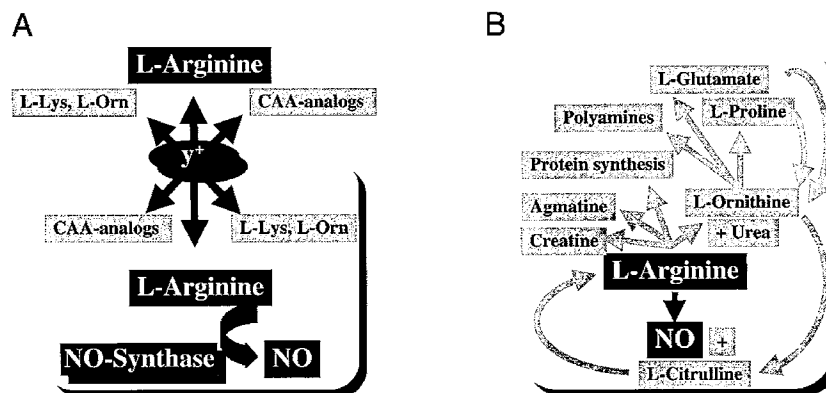

Figure 1 Factors influencing L-arginine availability for nitric oxide synthases in intact mammalian cells. (A) Transport through the plasma membrane. In NO-producing cells, transport of L-arginine is predominantly mediated via facilitated diffusion through cationic amino acid (CAA)-preferring carrier proteins (system y⁺). Consequently, other CAA and CAA analogs compete with L-arginine for transport via these carrier proteins. As CAA are exchanged with one another, the intracellular concentration of L-arginine will depend not only on its extracellular concentration, but also on the concentration of the other CAA. (B) Utilization and synthesis of L-arginine. L-arginine is consumed by metabolic pathways other than NO synthases (indicated by straight arrows), for example, protein and urea synthesis, the latter giving rise to L-ornithine, an important precursor for polyamines, L-proline, and L-glutamate. Some cells, on the other hand, can recycle L-arginine (indicated by curved arrows), from L-citrulline or even L-ornithine and L-glutamate.

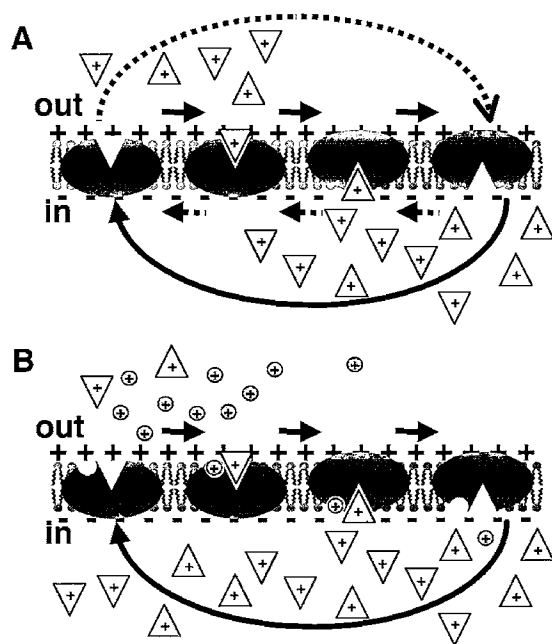

Figure 2 Scheme of carrier-mediated transport of cationic amino acids through the plasma membrane. (A) Facilitated diffusion. Cationic amino acid (CAA) fluxes through energy-independent carriers occur in both directions, into the cell (solid straight arrows) and out of the cell (dashed straight arrow). Net transport of substrate (shaded triangles) is only achieved when an unloaded carrier returns to its starting position after undergoing a conformational change (curved arrows). Although there is no direct coupling of solute transport with transport of an ion down its concentration gradient, CAA are still concentrated intracellularly due to the negative membrane potential of the cell. (B) Energy-dependent transport. These carrier proteins couple solute transport to the cotransport of one or several ions, using the ion gradient as the driving force to allow a greater concentration of substrate in the cell. The ion gradient directs this transport process in one direction (solid arrows).

characterized in fibroblasts (see review by White, 1985). Accumulating evidence indicates that L-arginine shares at least six different transport systems with other CAA (e.g., L-lysine and L-ornithine; see review by Deves and Boyd, 1998, and Van Winkel and Campione, 1990) and cationic NOS inhibitors (Baydoun and Mann, 1994; Schmidt *et al.*, 1994; McDonald *et al.*, 1997a). Five of these systems are Na^+ independent with respect to CAA and differ only in their interaction with NAA. CAA transport via system y^+ is saturable [Michaelis–Menten constant (K_m) of $\sim 80\text{--}100\ \mu\text{M}$], pH independent, and stimulated by substrate at the *trans*-side of the plasma membrane (*trans*-stimulation). In the presence of extracellular Na^+ , small NAA can inhibit system y^+ -mediated transport activity (e.g., L-homoserine but not L-leucine). Inhibition is not observed when Na^+ is replaced by K^+ , suggesting that Na^+ binds to the site that normally accepts the cationic side chain of a CAA (see review by White, 1985). The transport activity of system y^+ is increased during membrane hyperpolarization, implying that in the vascular endothelium most vasoactive agonists will stimulate entry of L-arginine (Bogle *et al.*, 1991; Bussolati *et al.*, 1993; Sobrevia *et al.*, 1995; Zharikov *et al.*, 1997). With the excep-

tion of the liver, system y^+ is expressed ubiquitously, and the majority of studies in endothelial, smooth muscle, and macrophage cell types have confirmed that L-arginine and other cationic analogs and NOS inhibitors are predominantly transported via a Na^+ -independent system with characteristics of the classic system y^+ (Bogle *et al.*, 1991, 1992a; Greene *et al.*, 1993; Wu and Meininger, 1993; Baydoun and Mann, 1994; Schmidt *et al.*, 1994; Block *et al.*, 1995; Sobrevia *et al.*, 1995, 1996; Wileman *et al.*, 1995; Bogle *et al.*, 1996; Sobrevia and Mann, 1997). Interestingly, in human endothelial cells system y^+ transport activity is increased in cells obtained from gestational diabetic pregnancies or exposed to elevated D-glucose for 3–12 hours (Sobrevia *et al.*, 1996, 1997; Sobrevia and Mann, 1997). System y^+ -like transport activity has also been described in astrocytes and cultured neuronal cells (Westergaard *et al.*, 1993; Schmidlin and Wiesinger, 1995; Schmidt *et al.*, 1995; Wayte *et al.*, 1996). As in the macrophage cell lines J774 and RAW 264.7 and in endothelial cells (Baydoun and Mann, 1994; Schmidt *et al.*, 1994; Bogle *et al.*, 1995), studies in a neuroblastoma/glioma hybrid cell line have confirmed that CAA and N^G -monomethyl-L-arginine (L-NMMA) are transported via system y^+ , whereas N^G -nitro-L-arginine (L-NNA) is taken up by NAA transport systems (Schmidt *et al.*, 1995). As described below, the role of other distinct Na^+ -independent CAA transport systems in NOS expressing cells has been characterized far less rigorously.

Transport of CAA via systems b_1^+ and b_2^+ has been described in preimplantation mouse conceptus (Van Winkel and Campione, 1990). Neither system is inhibitable by L-homoserine or L-leucine even in the presence of Na^+ . Both systems demonstrate a higher affinity for L-arginine relative to L-lysine; the preference for L-arginine is most pronounced for system b_2^+ , which exhibits a 100-fold lower K_m for L-arginine (about $80\ \mu\text{M}$) than for L-lysine. In addition, both systems recognize L-arginine with a higher affinity than L-homoarginine, in direct contrast to the classic system y^+ . As systems b_1^+ and b_2^+ have only been described in mouse preimplantation conceptus, these CAA transport systems most likely will not play a major role in modulating the L-arginine transport in NO-producing cells.

System y^+L , originally identified in human erythrocytes and subsequently in intestine and placenta (Deves *et al.*, 1992; Harvey *et al.*, 1993; Fei *et al.*, 1995), exhibits a much higher affinity for CAA (K_m for lysine $\sim 10\ \mu\text{M}$) than any other cationic transport system (see review by Deves and Boyd, 1998). System y^+L mediates Na^+ -independent CAA and Na^+ -dependent NAA transport. An additional difference between this system and systems y^+ , b_1^+ , and b_2^+ is the similar affinity of system y^+L for CAA and NAA (e.g., L-leucine, L-methionine, or L-glutamine) in the presence of Na^+ or Li^+ . Entry of L-lysine through this system is unaffected by removal of Na^+ , whereas the affinity of system y^+L for CAA is markedly decreased on substitution of extracellular Na^+ by K^+ (Deves *et al.*, 1992). *N*-Ethylmaleimide ($200\ \mu\text{M}$) has been used as a relatively selective inhibitor of system y^+ in erythrocytes and peripheral blood mononuclear

cells, permitting resolution of cationic amino acid influx via systems y^+L and y^+ (Deves *et al.*, 1993; Hanssen *et al.*, 1998). Moreover, as L-leucine does not interact with system y^+ , b_1^+ , or b_2^+ this amino acid can be used to selectively inhibit CAA transport by system y^+L in the presence of Na^+ (see review by Deves and Boyd, 1998). In all tissues where system y^+L activity has been observed, maximal rates of transport mediated by this system are low, indicating either a low capacity and/or a low expression of the carrier protein(s). In epithelial cells such as the small intestine and the renal proximal tubule, system y^+L is preferentially localized to the basolateral membrane and serves as an efflux pathway for CAA reabsorbed across the brush border membrane (Novak *et al.*, 1997; see also review by Deves and Boyd, 1998). Although the role of system y^+L in nonepithelial cells such as erythrocytes, peripheral blood mononuclear cells, and platelets is less well defined, an inwardly directed Na^+ gradient under physiological conditions would favor efflux of intracellular CAA in exchange for entry of NAA and Na^+ . Experiments *in vitro* have characterized influx and efflux of CAA via system y^+L (Deves *et al.*, 1992, 1993; Mendes Ribeiro *et al.*, 1997, 1999; Hanssen *et al.*, 1998; for review, see Deves and Boyd, 1998), and experiments in human platelets have established that L-arginine transport via system y^+L is stimulated in cells from patients with chronic renal failure (Mendes Ribeiro *et al.*, 1999). Unfortunately, virtually no information is available on the potential role of this transport system in NO-producing cells (see later).

System $b^{0,+}$ initially described in early mouse embryos has also been described in small intestinal and renal tubule epithelia, where it localizes to the apical membrane (Van Winkle *et al.*, 1988; Magagnin *et al.*, 1992; see review by Deves and Boyd, 1998). Transport of both CAA and NAA via system $b^{0,+}$ is Na^+ independent, with CAA and large α - and β -C atom unbranched NAA as the preferred substrates. Under physiological conditions, system $b^{0,+}$ recognizes CAA and NAA with similar affinity; however, in nonionic solutions (e.g., sucrose) the K_m for L-lysine is 10-fold lower than in isotonic salt solutions (about 60 μM), whereas the K_m for L-leucine is similar in both solutions (90–140 μM). Limited system $b^{0,+}$ transport activity has been observed in cultured vascular endothelial cells (Greene *et al.*, 1993; Pan *et al.*, 1995). In human umbilical vein endothelial cells (HUVEC), system y^+ represents the predominant entry pathway for CAA, since addition of L-leucine (10 mM) inhibits total Na^+ -independent L-arginine uptake by only 15–20% (Pan *et al.*, 1996; Sobrevia *et al.*, 1996, 1997; Sobrevia and Mann, 1997). Similar studies in cultured porcine pulmonary artery endothelial cells have confirmed system y^+ as the key Na^+ -independent transport pathway for CAA, although a Na^+ -independent uptake mechanism for L-arginine resembling system $b^{0,+}$ but with lower affinity for CAA has also been described (Greene *et al.*, 1993).

To date, system $B^{0,+}$, as originally described in blastocytes (Van Winkle *et al.*, 1985), represents the only Na^+ -dependent transport system described for CAA, and its activity has usually been identified in the same tissues as

system $b^{0,+}$. The substrate specificity of the two systems is similar; however, system $B^{0,+}$ also accepts small NAA (L-alanine, L-serine) and NAA that are branched at the α and β carbon atom {e.g., 2-aminobicyclo[2.2.1]heptane-2-carboxylic acid (BCH)}. System $B^{0,+}$ and $b^{0,+}$ transport activities have been described in porcine cultured pulmonary artery endothelial cells (Greene *et al.*, 1993; Block *et al.*, 1995). In the latter study, hypoxia was shown to decrease L-arginine transport by both system y^+ and $B^{0,+}$, yet the authors did not investigate whether decreased L-arginine transport via these transport systems limited NO production. To our knowledge, the involvement of systems $B^{0,+}$ and $b^{0,+}$ in modulating NO synthesis remains to be investigated.

Activation of Cationic Amino Acid Transport in Inflammation

Numerous studies have implicated NO as a cytokine-induced vasodilator in bacterial sepsis (see review by Knowles and Moncada, 1994). A Ca^{2+} -independent isoform of NO synthase (NOS II), as first described in macrophages (Hibbs *et al.*, 1988), has been identified in endothelial cells exposed to tumor necrosis factor α (TNF- α) and γ -interferon (IFN- γ) or bacterial lipopolysaccharide (LPS). Induction of NOS II occurs with a lag period reaching a maximum usually between 6 and 12 hours, is inhibited by glucocorticoids, and is dependent on a supply of extracellular L-arginine (Hibbs *et al.*, 1987; Bogle *et al.*, 1992b; for review, see Knowles and Moncada, 1994).

Experiments in the human endothelial cell line SGHEC-7 have shown that treatment with LPS for 6 hours caused parallel increases in CAA transport and production of nitrite, the stable breakdown product of NO (Bogle *et al.*, 1995). This report confirmed findings from similar studies in J774 macrophages and rat aortic smooth muscle cells (Baydoun *et al.*, 1993; Wileman *et al.*, 1995), where activation of transport of L-arginine and the cationic arginine analog L-NMMA by LPS was blocked by cycloheximide but unaffected by dexamethasone. In contrast, studies in rat pulmonary endothelial cells concluded that dexamethasone inhibited Na^+ -independent L-arginine transport (Pan *et al.*, 1996), although the inhibitory effects of dexamethasone on NO production were not assessed in parallel. In other endothelial cell types, LPS activated system y^+ through an autocrine release of the cytokines TNF- α and interleukin-1 (IL-1), since pretreatment of cells with either an anti-TNF antibody or a IL-1 receptor antagonist significantly inhibited LPS-stimulated L-arginine transport (Cendan *et al.*, 1996). In this study, activation of L-arginine influx required protein synthesis and was apparently mediated via the Na^+ -independent systems y^+ and the Na^+ -dependent system $B^{0,+}$, with little or no change detected in system $b^{0,+}$ activity.

Earlier studies in cultured macrophages established that L-arginine supply was rate limiting for sustained NO synthesis in cytokine-activated cells (Hibbs *et al.*, 1987). More

recent reports based on studies in arterial ring preparations or cultured J774 macrophages and vascular smooth muscle cells have confirmed this observation, and they implicated L-arginine transport as a rate-limiting factor for NO production (Bogle *et al.*, 1992b; Schott *et al.*, 1993; Wileman *et al.*, 1995; Durante *et al.*, 1996). However, over shorter time intervals (2 min), NO production in the macrophage cell line J774 has been shown to be independent of extracellular L-arginine (Closs *et al.*, 1999).

Carrier Proteins Identified on the Molecular Level

Although the existence of specific carrier systems in the plasma membrane of mammalian cells has been documented for many years, identification of the corresponding proteins mediating the respective transport activities remains a challenge. It is only relatively recently that cDNAs encoding specific CAA carrier proteins have been cloned. Some of these have been cloned by serendipity or as a result of their homology to other carrier proteins, whereas others were identified by expression cloning. The proteins encoded by these cDNAs belong to three different families [solute carrier families (SLC) 3, 6, and 7, see Table I] and mediate transport activities resembling systems y^+ , y^+L , $b^{0,+}$, or $B^{0,+}$ when overexpressed in *Xenopus laevis* oocytes or in mammalian cells. The molecular identification of these carrier proteins revealed an even greater diversity than had been anticipated from radiotracer flux experiments. The protein(s) responsible for the activity of system(s) b^+ has as yet not been identified.

Cationic Amino Acid Transporters

STRUCTURE AND FUNCTION OF THE CAT PROTEINS

The CAT proteins belong to the first amino acid carriers discovered in mammalian cells. Albritton and co-workers (1989) obtained a cDNA encoding the first family member when they identified the protein responsible for susceptibility to infection by murine ecotropic leukemia viruses (MuLV). Similarities between the secondary structure of the MuLV receptor and L-histidine and L-arginine permeases from *Saccharomyces cerevisiae* suggested that this protein may also function as a solute transporter. Expression of the ecotropic MuLV receptor in *Xenopus laevis* oocytes and subsequent transport studies demonstrated that this receptor mediates Na^+ -independent transport of cationic amino acids (Kim *et al.*, 1991; Wang *et al.*, 1991). Thus, the virus receptor was renamed mCAT-1 (mouse cationic amino acid transporter). mCAT-1 is an integral membrane protein with 14 putative transmembrane domains and intracellular N- and C-termini (Fig. 3A). Four additional related proteins, named CAT-2A, -2B, -3, and -4, have since been identified in different mammalian species including humans (see Table I and references therein), with CAT-2A and -2B being splice variants that differ only in a stretch of 42 amino acids (Closs *et al.*, 1993a, 1997a; Kavanaugh *et al.*, 1994). The amino acid

sequences of CAT-2A, -2B, and -3 are more closely related to each other than to CAT-4 (Table II). All known CAT proteins exhibit quite similar hydrophobicity plots, suggesting that their structure in the membrane is also similar. Consensus sequences for N-linked glycosylation can be found in each isoform but at different locations (see Fig. 3). CAT-1, -2A, and -2B have been shown to be glycosylated, indicating that these carriers are in fact located in the plasma membrane (Closs *et al.*, 1993b,c; Kim and Cunningham, 1993).

As evidenced by studies to date, all CAT proteins mediate Na^+ -independent transport of CAA (see Table I and references therein). However, they differ in their transport properties. Mouse, rat, and human CAT-1, -2A, and -2B isoforms have been characterized in greatest detail. Their transport properties have been investigated in *Xenopus laevis* oocytes, where each carrier can be expressed individually and its activity studied against a low background of endogenous CAA transport. In this model system transport activity has been assayed either using radiolabeled amino acids or measuring amino acid-induced membrane currents by whole cell voltage clamp. Transfection of mammalian cells with expression vectors encoding the various CAT isoforms has also been employed to determine CAT activity. However, in general only a moderate increase in the transport rate of CAA has been observed in mammalian cells, even when using a strong promoter for the expression of CAT encoding cDNAs. It is worth noting that cells cultured *in vitro* usually express at least CAT-1, and hence it is not always feasible to unambiguously distinguish exogenous and endogenous transport activities.

Apparent K_m values for influx of L-arginine reported by different groups for CAT proteins expressed in *Xenopus laevis* oocytes are 70–250 μM for CAT-1, 2–5 mM for CAT-2A, and 38–380 μM for CAT-2B (Kim *et al.*, 1991; Wang *et al.*, 1991; Closs *et al.*, 1993a,b, 1997a; Kakuda *et al.*, 1993; Kavanaugh *et al.*, 1994). K_m values for the cationic amino acids L-lysine and L-ornithine are similar to those reported for L-arginine, suggesting that these three substrates be recognized with similar affinity. However, for CAT-2B an about two- to threefold lower affinity to L-ornithine as compared to L-arginine and L-lysine has been reported (Kakuda *et al.*, 1993; Kavanaugh *et al.*, 1994). The selectivity of CAT-1 for transport of dibasic amino acids is shown by the pH dependence of L-histidine transport (Kim *et al.*, 1991). At pH 7.4, L-histidine is a poor substrate for CAT-1, most likely because at neutral pH most L-histidine is a dipolar amino acid. In contrast, at pH 5.5, when L-histidine is largely protonated, transport rates for L-histidine via CAT-1 are similar to rates measured for L-arginine. Mouse and rat CAT-3 have also been shown to mediate Na^+ -independent transport of CAA with the apparent K_m for L-arginine ranging from 40 to 120 μM (Hosokawa *et al.*, 1997; Ito and Groudine, 1997). However, the maximal transport activity (V_{max}) of CAT-3 expressed in *Xenopus laevis* oocytes is considerably lower than that of the aforementioned isoforms (0.02–0.06 versus 1–8 nmol/oocyte/hour; Ito and Groudine, 1997). The reason for this low activity is not readily apparent. In addition, the

Table I Carrier Proteins Involved in the Transport of L-Arginine^a

^a This table lists the carrier proteins identified to date at the molecular level that are involved in the transport of CAA. These carrier proteins belong to three different gene families and were largely characterized in transport studies in *Xenopus laevis* oocytes expressing the respective carrier protein.

^b For references for the transport systems, see review by Deves and Boyd (1998).

^c Names given in parentheses refer to alternative names also found in the literature.

^d Histidine transport by CAT-1 and CAT-2B is only partially Na⁺ dependent, because a small fraction of this amino acid is protonated at neutral pH and therefore behaves like CAA.

^e Interaction of NAA with CAT-3 has been investigated by inhibition studies of L-arginine uptake conducted in COS cells and *Xenopus laevis* oocytes. Hosokawa *et al.* (1997, using ~10⁴-fold excess competitor) found no cross-inhibition by any of the neutral or acidic amino acids except for L-citrulline. In contrast, Ito and Groudine (1997), using ~10⁶-fold excess competitor, detected Na⁺-independent inhibition by L-methionine, L-cysteine, as well as L-aspartic and L-glutamic acid.

^f Transport properties have only been characterized for rBAT expressed in *Xenopus laevis* oocytes where it forms heterodimers with an endogenous protein. Transport studies on rBAT coexpressed with the newly identified b^{0,+} AT have not yet been reported.

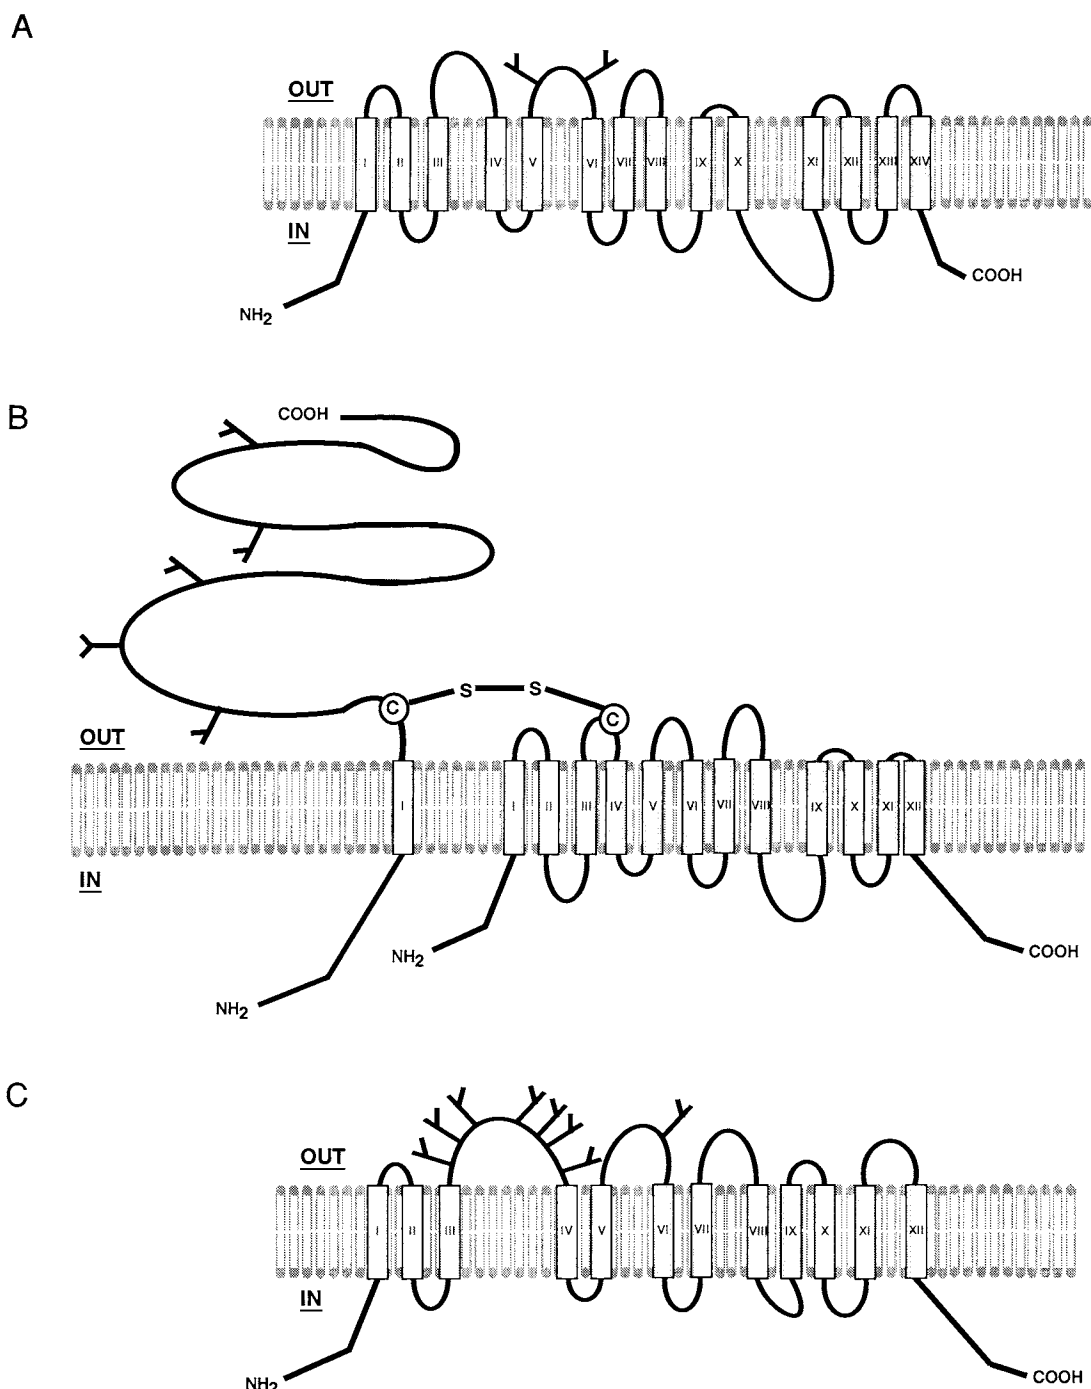

Figure 3 Schematic representation of carrier proteins involved in the transport of cationic amino acids. (A) Model of CAT-1 as an example for the CAT proteins. The members of the CAT family are glycosylated proteins with 14 putative transmembrane domains (TMs). Alternative models suggesting 12 or 13 TMs have also been proposed. Two asparagine residues in the third extracellular loop (indicated as branched lines) have been shown to be glycosylated in mCAT-1. These sites are conserved in CAT-2A and 2-B. In addition, there is one putative glycosylation site in the second extracellular loop of CAT-2A and 2-B. In contrast, only one consensus site for N-glycosylation located in the third extracellular loop is found in CAT-3. The three putative glycosylation sites of CAT-4 are located in the second, third, and sixth extracellular loop. (B) Model of 4F2hc and y⁺LAT-1 as an example for the heterodimeric cationic amino acid carriers. 4F2hc and rBAT are distantly related glycoproteins. Only one typical α -helical TM is found in 4F2hc and rBAT, suggesting they are type II membrane proteins with an intracellular N terminus and an extracellular C terminus. An alternative model with three additional amphipathic TMs and an intracellular C terminus has been proposed for rBAT (Mosckovitz *et al.*, 1994). Cys¹⁰⁹ in human 4F2hc has been shown to form a sulfur bridge with y⁺LAT-1. This residue is conserved in rBAT. The associated carrier proteins (y⁺LAT-1, -2, and 4F2-1c6 for 4F2hc and b⁰+AT for rBAT, respectively) are predicted to span the membrane 12 times. Although they are distantly related to the CAT proteins, these carrier proteins are not glycosylated and require an association with glycoproteins to translocate to the plasma membrane. A cysteine residue in the second extracellular loop conserved in y⁺LAT-1, -2, and b⁰+AT has been proposed to form a sulfur bridge with 4F2hc and rBAT, respectively. (C) Model of ATB⁰⁺. ATB⁰⁺ belongs to the family of Na⁺/Cl⁻-dependent neurotransmitter transporters. It contains 12 putative TMs and eight consensus sites for N-glycosylation in the second and third putative extracellular loop.

Table II Sequence Comparison between the Human CAT Proteins^a

	hCAT-1	hCAT-2A	hCAT-2B	hCAT-3 ^b	hCAT-4
hCAT-1	—	60	62	61	41
hCAT-2A	54	—	96	58	42

hCAT-4	51	52	43	43	—

^aThis table compares the amino acid sequences of the five human CAT isoforms identified to date. Boldface numbers list the percent identity after an optimal alignment of the complete amino acid sequence. The numbers not in bold face list the percent identity after an optimal alignment of the short amino acid sequence that differs between CAT-2A and CAT-2B. Sequences were aligned using the NCBI BLASTP program.

^bhCAT-3 sequence from N. Vékony and E. I. Closs, unpublished data.

substrate selectivity of CAT-3 seems to differ somewhat from that reported for the other CAT isoforms. The transport properties of CAT-4 have not yet been investigated.

In addition to the Na⁺-independent CAA transport mediated by CAT-1 and CAT-2B, these carriers also mediate Na⁺-dependent transport of some NAA, but with rather low affinity (Wang *et al.*, 1991; Kakuda *et al.*, 1993). CAT-3-mediated L-arginine transport is competitively inhibited not only by other CAA but also by L-citrulline, D-arginine (Hosokawa *et al.*, 1997), L-methionine, L-cysteine, and even L-aspartate and L-glutamate, but not by L-homoserine (Ito and Groudine, 1997). In contrast to CAT-1 and -2B, recognition of NAA by CAT-3 has been found to be Na⁺ independent. However, in these studies potential competitor amino acids were used at 10⁴ to 10⁶ higher concentrations than the substrate, and transport inhibition was only 50–75%, raising the question whether these putative inhibitor interactions were specific.

The CAT proteins differ also in their sensitivity to *trans*-stimulation. Whereas the activities of CAT-1 and -2B are stimulated by physiological concentrations of substrate at the *trans*-side of the plasma membrane (100–250 μ M), transport mediated by CAT-2A is largely independent of the presence of substrate at the *trans*-side of the membrane (Closs *et al.*, 1993b, 1997b). The most pronounced *trans*-stimulation has been observed for CAT-1. In the case of mCAT-3, *trans*-stimulation was about twofold at a *trans*-membrane substrate concentration of 10 mM compared to zero substrate concentration (Ito and Groudine, 1997).

For mCAT-1 a voltage dependence of CAA transport has been described; membrane hyperpolarization increases the V_{\max} and decreases the apparent K_m for influx, and it decreases the V_{\max} and increases the apparent K_m for efflux (Kavanaugh, 1993). Changes in the membrane potential may thus result in changes in the transport rate for L-arginine, as evidenced by numerous radiotracer flux studies in cultured cells (Bogle *et al.*, 1991; Bussolati *et al.*, 1993; Sobrevia *et al.*, 1995; Zharikov *et al.*, 1997). The voltage dependence of the other CAT isoforms has not yet been investigated.

The transport properties of CAT-1, -2B, and -3 are consistent with those originally attributed to the classic system y⁺. In contrast, CAT-2A is a low-affinity carrier for CAA that is relatively insensitive to *trans*-stimulation. It is remarkable that CAT-2A and -2B demonstrate such divergent transport properties, even though their amino acid sequences are 96% identical and differ only in a stretch of 42 amino acids. According to the 14 transmembrane model, this protein domain is located in the fourth intracellular loop. Replacement of the corresponding region of mCAT-1 by that of mCAT-2A or -2B and vice versa leads to chimeric proteins with transport properties of the donor of that region (including the apparent affinity for L-arginine and sensitivity to *trans*-stimulation; Closs *et al.*, 1993a). Interestingly, in that region the three isoforms exhibiting similar transport properties (CAT-1, -2B, and -3) also show the highest percentage of amino acid sequence identity (Table II).

CAT EXPRESSION IN NO-PRODUCING CELLS

System y⁺ seems to be the major transport system for L-arginine in most NO-producing cells. In addition, the activity of system y⁺ has been found to increase in response to exogenous stimuli such as LPS, IL-1 β , TNF- α , insulin, angiotensin II, and bradykinin in a variety of cell types (Bogle *et al.*, 1991, 1992b; Lind *et al.*, 1993; Durante *et al.*, 1995, 1996; Pan *et al.*, 1995; Schmidlin and Wiesinger, 1995; Wilerman *et al.*, 1995; Cendan *et al.*, 1996). Recent findings suggest that this is, at least in part, due to a differential induction of CAT gene expression in these cells (see Table III and references therein). In most studies the expression of CAT-1, -2A, and -2B mRNA has been examined, whereas only little information is available for the more recently discovered isoforms CAT-3 and -4. CAT-1 expression has been found in all cell types investigated, which is consistent with the presence of system y⁺ transport activity deduced from radiotracer flux experiments (Table III and references therein). CAT-2B expression has been shown in macrophages and glial cells activated with LPS or LPS and IFN- γ (Closs *et al.*, 1993b, 1999; Stevens *et al.*, 1996; Kakuda *et al.*, 1999), in vascular smooth muscle cells (VSMC) induced

Table III Expression of the Carrier Proteins Involved in the Transport of L-Arginine^a

Carrier	Constitutive expression	Upregulation of expression	References
CAT proteins

^aThis table summarizes data based on studies of the expression of the respective mRNAs and where available the protein.

^bNames given in parentheses refer to alternative names reported in the literature.

^cmRNA was only detected by RT-PCR and not by less sensitive methods like RNase protection analysis or Northern blots (MacLeod *et al.*, 1990).

^dIn these studies, no distinction between CAT-2A and CAT-2B expression has been made. We assume here that it is the high affinity isoform (CAT-2B) that was induced.

^en.d.: not determined.

either with IL-1 β and TNF- α (Gill *et al.*, 1996), with lyso-phosphatidylcholine (LPC; Durante *et al.*, 1997), or with LPS and IFN- γ (Baydoun *et al.*, 1999; Hattori *et al.*, 1999), in cardiac myocytes and cardiac microvascular endothelial cells (CMEC) exposed to IL-1 β and IFN- γ (Simmons *et al.*, 1996), and in HUVEC stimulated with TNF- α (Irie *et al.*, 1997). In most cell types a significant expression of CAT-2B is found only after cytokine or LPS treatment. CAT-2B has therefore been referred to as the inducible CAT isoform. It is generally coexpressed with the more constitutive CAT-1 isoform. However, expression of CAT-1 can also be induced in response to external stimuli such as angiotensin II (Low and Grigor, 1995), platelet-derived growth factor (Duran-*et al.*, 1996), LPS combined with IFN- γ (Baydoun *et al.*, 1999; Hattori *et al.*, 1999), and it can be induced moderately by LPC (Duran-*et al.*, 1997) in VSMC, by insulin, IL-1 β , and IFN- γ in cardiac myocytes, by amino acid starvation or glucocorticoids and insulin in hepatoma cells (Hyatt *et al.*, 1997; Liu and Hatzoglou, 1998), and in hepatocytes *in vivo* by dexamethasone, insulin, L-arginine, low protein diet, and regeneration of the liver (Wu *et al.*, 1994; Aulak *et al.*, 1996). In addition, CAT-1 expression has been shown to increase with cell proliferation in a variety of cell types (Yoshimoto *et al.*, 1992). The induction of CAT-1 mRNA has been shown to occur at both the transcriptional and posttranscriptional levels. In amino acid-starved FAO hepatoma cells and in regenerating liver, CAT-1 mRNA is induced without change of the transcription rate (Aulak *et al.*, 1996; Hyatt *et al.*, 1997), whereas the induction of CAT-1 by glucocorticoids and insulin in quiescent liver is due to both an increase in the transcription rate and stabilization of the mRNA (Liu and Hatzoglou, 1998).

The expression of CAT-2B is often induced together with NOS II, the inducible isoform of NO synthase. The signaling pathways leading to induction of CAT expression are at least in part distinct from those leading to induction of NOS II (see Fig. 4). In VSMC activation of p38 mitogen-activated protein kinase (p38 MAPK) represents an important signaling mechanism, regulating both enhanced L-arginine transport and induced NO synthesis, whereas protein tyrosine kinases (PTK) appear to be involved in the induction only of NOS II and not of CAT expression (Baydoun *et al.*, 1999). In RAW 264 macrophages, LPS but not IFN- γ induces CAT-2B expression, whereas NOS II is induced with similar efficacy by both compounds (E. I. Closs, unpublished observation). Surprisingly, expression of the low-affinity carrier CAT-2A, in addition to CAT-1 and -2B, has been found in cardiomyocytes and CMEC stimulated with IL-1 β and IFN- γ (Simmons *et al.*, 1996), as well as in VSMC treated with LPS and IFN- γ (Baydoun *et al.*, 1999). The physiological role of a carrier with a K_m for cationic amino acids ≥ 2 mM is not evident in cells that are normally exposed to plasma with a CAA concentration of about 0.2 mM. The expression of CAT-3 is found in mesoderm and in many developing tissues of mid streak mouse embryos, but it seems to be confined to the brain in adult animals (Hosokawa *et al.*, 1997; Ito and Groudine, 1997). Studies in rat brain provide evidence for the localization of CAT-3 mRNA in

Figure 4 Differential expression of cationic amino acid transporters and NOS II in different cell types. (A) Macrophages. In RAW and J774 murine macrophages exposure to lipopolysaccharide (LPS), but not γ -interferon (IFN- γ), leads to an increase in L-arginine transport activity (Bogle *et al.*, 1992b; Baydoun and Mann, 1994) and an induction of CAT-2B expression (Closs *et al.*, 1993a, 1999; Kakuda *et al.*, 1999). In contrast, both LPS and IFN- γ induce the expression of NOS II. Dexamethasone (Dex) inhibits the induction of NOS II but not of CAT-2B. CAT-1 expression is detected in unstimulated macrophages and does not change in response to LPS or IFN- γ . (B) Vascular smooth muscle cells. In rat cultured vascular smooth muscle cells CAT-1, -2A, and -2B are expressed under basal conditions. The expression of all three isoforms, as well as NOS II, is increased on exposure of the cells to LPS and IFN- γ , with a concomitant increase in L-arginine transport and NO release (Wileman *et al.*, 1995; Baydoun *et al.*, 1999). Activation of p38 mitogen-activated protein kinase (p38 MAPK) represents an important signaling mechanism, regulating both enhanced CAT and NOS II expression, whereas protein tyrosine kinases (PTK) are involved in the induction of NOS II but not of CAT expression (Baydoun *et al.*, 1999).

specific neurons but not glial or endothelial cells (Hosokawa *et al.*, 1999; Braissant *et al.*, 1999). In contrast, CAT-1 presents ubiquitous neuronal and glial expression (Braissant *et al.*, 1999), and a study in neuronal cultures derived from rat hypothalamus/brain stem attributed basal rates of L-arginine transport principally to CAT-1 activity (Stevens and Vo, 1998). Similar to CAT-3, CAT-4 is expressed in the brain but also in testis and placenta (Sperandeo *et al.*, 1998). The cell type(s) expressing CAT-4 in these tissues has not yet been identified.

In contrast to mRNA expression, little information is available concerning protein expression of the CAT. In most cell types investigated to date the increase in L-arginine transport in response to external stimuli is considerably less than the observed increase in CAT mRNA expression. This suggests either that the mRNA is not translated into protein

or that a large portion of the newly synthesized carriers is not active. Evidence for a silent system y^+ -like carrier comes from studies in rabbit and rat peritoneal macrophages, where the transport rate for L-arginine can be increased up to 10-fold by a treatment with the protein kinase C (PKC) activating phorbol ester [phorbol-12-myristate-13-acetate (PMA)] without the need for protein synthesis (Racke *et al.*, 1998). We have found that the activity of CAT-1 decreased in response to PMA with no change in the protein expression both in *Xenopus laevis* oocytes and in human endothelial cells, suggesting that different PKC isoforms might have a differential effect on the CAT activity (P. Gräf, H. Li, U. Förstermann, and E. I. Closs, unpublished data). To address the question of whether CAT activity is under posttranslational control, the expression and subcellular localization, as well as possible posttranslational modifications of the CAT-proteins, will need to be investigated.

SUBSTRATE SUPPLY FOR NOS BY THE CAT PROTEINS

As CAT-2B is often induced together with NOS II, it has generally been assumed that CAT-2B specifically delivers L-arginine to NOS II. However, no direct evidence has been provided in support of this hypothesis. A specific role for CAT-1 in providing substrate for the endothelial isoform of NOS (NOS III) has been proposed, based on immunostaining of porcine endothelial cells, which suggests a colocalization of CAT-1, NOS III, and caveolin-1 in endothelial caveoli (McDonald *et al.*, 1997b). In support of this hypothesis, we found that the NOS III activity was decreased in human endothelial cells after PMA-induced downregulation of L-arginine transport (P. Gräf, H. Li, U. Förstermann, and E. I. Closs, unpublished data). However, the effect of PMA on transport was much greater than its effect on NOS activity, demonstrating that NOS III is still active, even when L-arginine transport was reduced to 5 to 10% of the control transport rate. In contrast to inducing CAT-1 and CAT-2B mRNA expression and L-arginine transport in smooth muscle cells, LPC has been reported to inhibit the high-affinity component of the L-arginine transport (presumably CAT-1) in aortic endothelial cells (Kikuta *et al.*, 1998). LPC also inhibited NO release induced by ADP in these cells, and this inhibition could be attenuated by excess extracellular L-arginine, suggesting that the impairment of CAT-1 might account for the inhibition of NOS III by LPC. Functional knockouts of individual CAT isoforms will be necessary to elucidate the function of each isoform in supplying the substrate L-arginine for NOS. A germ-line null mutation has been introduced into the mCAT-1 gene by targeted mutagenesis of embryonic stem cells (Perkins *et al.*, 1997). The homozygous knockout mice die on day 1 after birth, exhibit a 25% reduction in size compared to the wild-type littermates, and suffer from severe anemia. Unfortunately, no information is available on the activity of NOS in the different cell types of these mice.

Besides transporting L-arginine, CAT proteins also mediate the transport of some L-arginine analogs. In agreement with earlier studies on system y^+ (Baydoun and Mann, 1994; Schmidt *et al.*, 1994), the substrate specificity of the CAT

proteins for L-arginine analogs differs markedly from that of the inducible NOS II (Closs *et al.*, 1997b). Thus, there are some NOS inhibitors that are recognized and transported by the CAT proteins [e.g., L-NMMA, L- N^5 -(1-iminoethyl)-ornithine (L-NIO) or asymmetrical N^G, N'^G -dimethyl-L-arginine (L-ADMA)], whereas others such as L-NNA and its methyl ester N^G -nitro-L-arginine methyl ester (L-NAME) are not. The latter neutral arginine analogs enter most cell types via broad-specificity NAA transport systems (Baydoun and Mann, 1994; Schmidt *et al.*, 1994). In contrast, some L-arginine analogs are transported by the CAT proteins [e.g., symmetrical N^G, N'^G -dimethyl-L-arginine (L-SDMA), and α -amino- δ -isothioureidovaleric acid (AITV)], but they are not recognized by NOS and do not inhibit NOS activity directly. The different behavior of these arginine derivatives with respect to CAT-mediated transport is most likely due to differences in the charge of their side chain. Because of *trans*-stimulation, L-arginine analogs that are CAT substrates not only compete with L-arginine for influx, but also stimulate efflux of intracellular L-arginine and other cationic substrates. Therefore, compounds such as L-SDMA or AITV, which do not interfere with the NOS enzyme directly but limit substrate availability, may indirectly inhibit NOS activity in intact cells (see review by Closs and Gräf, 1999). However, as circulating levels of L-SDMA are only within the micromolar range, their inhibitory effects may well be restricted to system y^+L .

Heterodimeric Carrier Proteins for CAA

STRUCTURE AND FUNCTION OF THE HETERODIMERIC CARRIER PROTEINS

Transport activities resembling systems $b^{0,+}$ and y^+L are mediated by heterodimeric proteins consisting of two unrelated moieties: a glycosylated protein with a structure not typical for carrier proteins and a typical multimembrane spanning carrier protein (see Fig. 3). The first glycoprotein identified to be involved in amino acid transport was rBAT (related to $b^{0,+}$ amino acid transporter; for alternative names, see Table I and review by Palacin *et al.*, 1998). cDNAs encoding rBAT have been cloned by different groups from rabbit, rat, and human by functional expression of kidney mRNA in *Xenopus laevis* oocytes (see review by Palacin *et al.*, 1998, and references therein). rBAT expression in oocytes leads to a significant increase in the Na^+ -independent high-affinity transport of CAA, NAA, and cystine, a transport activity resembling system $b^{0,+}$, except that the latter does not mediate the transport of cystine. Mutations in the human rBAT gene leading to a defective or missing rBAT protein have been shown to be the cause for cystinuria type I, a recessive inherited disease with defect in renal and intestinal reabsorption of cystine and CAA (see review by Palacin *et al.*, 1998). The involvement of a Na^+ -independent transporter in epithelial reabsorption seems surprising. It can be explained, however, by the fact that the transport activity induced by rBAT is an obligatory exchanger of NAA and CAA (see Fig. 5). It has therefore been postulated that system $b^{0,+}$ /rBAT represents a tertiary active transport in the

Figure 5 Transport characteristics of carrier proteins for cationic amino acids. The CAT proteins mediate facilitated diffusion of CAA with very low affinity for neutral amino acids (NAA, not shown). CAT-1, -2B, and -3 exhibit a high affinity for CAA and are sensitive to *trans*-stimulation (system y^+ -like carriers). In contrast, CAT-2A is a low-affinity CAA carrier that is relatively insensitive to *trans*-stimulation. One or more CAT isoforms are expressed in nearly all cell types. rBAT most likely forms a heterodimer with b^0+ AT, mediating the obligatory exchange of CAA, cystine, and NAA, reminiscent of the transport activity assigned to system b^0+ . Owing to the negative membrane potential and the high intracellular concentration of NAA (which is due to Na^+ -dependent NAA carriers), it is proposed that CAA (and cystine, not shown) are preferentially transported into the cell in exchange for NAA (tertiary active transport). rBAT and presumably b^0+ AT are localized at the apical membrane of epithelial cells in the kidney and small intestine. ATB^{0+} transports CAA and NAA in a Na^+ - and Cl^- -dependent manner (system B^{0+} -like activity), and it is predominantly expressed in lung and salivary gland, but also in mammary gland, pituitary gland, and stomach. System B^{0+} has been shown to be located in the apical membrane of epithelial cells, and thus an apical localization also seems likely for ATB^{0+} . 4F2hc builds a heterodimer with y^+ LAT-1 and y^+ LAT-2 to form a transport system (y^+ L) that mediates Na^+ -independent transport of CAA and Na^+ -dependent transport of NAA. Similar to system b^0+ , y^+ L is also an obligatory exchanger. As a result of the Na^+ gradient encountered under physiological conditions, NAA are preferentially transported into the cell across the basolateral membrane in exchange for intracellular CAA. 4F2hc has been shown to be located at the basolateral membrane of epithelial cells in the kidney and small intestine. Therefore, system y^+ L seems to function as an export pathway for CAA, allowing the *trans*-epithelial flux of CAA in concert with transport systems operative in the apical membrane mediating accumulative uptake into the cell. The 4F2hc/4F2hc heterodimer, which is also expressed in small intestine and kidney and mediates b^0+ -like activity (Rajan *et al.*, 1999), is not shown.

epithelial cells, where NAA are concentrated by Na^+ -dependent carriers (secondary active transport), leading to high intracellular concentrations of NAA that are then exchanged against extracellular CAA and cystine (Busch *et al.*, 1994; Chillaron *et al.*, 1996). In addition, the uptake of CAA and cystine is favored because of the negative membrane potential and the intracellular reduction of cystine to cysteine.

Owing to homology to rBAT, the amino acid transport activity of a second glycoprotein (4F2hc or CD98), originally identified as a tumor antigen on lymphoblastoid cells, was assayed (Bertran *et al.*, 1992; Wells *et al.*, 1992). Expression of 4F2hc in *Xenopus laevis* oocytes leads to an increase in high-affinity transport of CAA (Na^+ -independent) and NAA (Na^+ -dependent), resembling transport activity attributed to system y^+ L. Interestingly, Bröer and coworkers

(1995) demonstrated that in rat C6 glioma cells 4F2hc is an essential component of system L, a Na^+ -independent system for large NAA, suggesting that 4F2hc might be involved in different transport activities.

Although both rBAT and 4F2hc induced amino acid transport activity when expressed alone in *Xenopus laevis* oocytes, there is convincing evidence that neither serves as a carrier protein but that each associates with a second protein to build the functional transporter. First, both proteins are predicted to span the membrane only once or, in an alternative model, four times (Mosckovitz *et al.*, 1994); both configurations are unusual structures for a carrier protein. Second, the transport activity of rBAT in *Xenopus laevis* oocytes does not correlate with the amount of protein expressed in the plasma membrane, suggesting that a second protein may be limiting (Estevez *et al.*, 1998). Third, both proteins have been shown to build heterodimers with non-glycosylated smaller proteins, referred to as light chains of the glycoproteins (see review by Palacin *et al.*, 1998). cDNAs encoding these smaller proteins have now been cloned. All proteins of this newly identified group are predicted to have 12 transmembrane domains (TMs) (see Fig. 3) and are distantly related to the CAT proteins; with amino acid sequences aligned optimally, identity lies in the range of 20%. Other than the CAT proteins, these are not glycosylated, and they localize to the plasma membrane and exhibit transport activity only when coexpressed with the respective glycoprotein. A conserved cysteine residue in the second putative extracellular loop is likely to form a disulfide bond with a conserved cysteine residue in rBAT and 4F2hc (Cys¹⁰⁹ and Cys¹⁰³ of human and mouse 4F2hc, Torrents *et al.*, 1998; Nakamura *et al.*, 1999). The first light chain (named LAT-1) was identified by independent groups in human, rat, and mouse. It mediates a system L-like activity when coexpressed with 4F2hc (Kanai *et al.*, 1998; Mastroberardino *et al.*, 1998; Nakamura *et al.*, 1999; Prasad *et al.*, 1999). More recently, five additional light chains were reported to mediate the activity of system L (LAT-2), y^+ L (y^+ LAT-1 and y^+ LAT-2), x_c^- (xCT, an exchanger for anionic amino acids, e.g., cystine and glutamate), and surprisingly b^0+ when associated with 4F2hc (Torrents *et al.*, 1998; Pfeiffer *et al.*, 1999; Pineda *et al.*, 1999; Sato *et al.*, 1999; Segawa *et al.*, 1999; Rajan *et al.*, 1999). Mutations in the human y^+ LAT-1 gene (SLC7A7) segregate with lysinuric protein intolerance (LPI), a heritable disorder associated with a defect of CAA transport in the basolateral membrane of epithelial cells in small intestine and renal tubules (Borsani *et al.*, 1999; Torrents *et al.*, 1999). Transport by 4F2hc/ y^+ LAT-1 is strongly *trans*-stimulated, suggesting that this transport agency is also an obligatory exchanger. As the transport of NAA is Na^+ dependent, NAA can only be transported into the cell due to the Na^+ gradient (Fig. 5). Very recently, a light chain associating with rBAT, named b^0+ AT, has been reported (Feliubadalo *et al.*, 1999). Consistent with system b^0+ , coexpression of rBAT/ b^0+ AT leads to a Na^+ -independent transport activity for NAA and CAA. Therefore, both rBAT and 4F2hc seem to mediate system b^0+ activity when associated

with the respective light chain (rBAT/b^{0,+}AT and 4F2hc/4F2-lc6, respectively). Mutations in the human gene for b^{0,+}AT (SLC7A9) segregate with non-type I cystinuria.

EXPRESSION AND PHYSIOLOGICAL ROLE OF THE HETERODIMERIC CARRIER PROTEINS INVOLVED IN CAA TRANSPORT

Much more information is available concerning the expression and function of the glycoproteins rBAT and 4F2hc than of the only recently discovered proteins that associate with them. rBAT mRNA has been shown to be expressed in small intestine and the proximal straight tubules of the kidney (see review by Palacin *et al.*, 1998). Ultrastructural analysis showed that rBAT localizes to the brush-border membrane of epithelial cells, which is consistent with its role in reabsorption of CAA and cystine (Pickel *et al.*, 1993). Furthermore, the observation that mutations of both rBAT and its associated protein b^{0,+}AT cause cystinuria (rBAT, type I cystinuria; b^{0,+}AT, non-type I cystinuria) is consistent with this function. Transcripts hybridizing with rBAT cDNA probes but larger than the mRNAs found in kidney and small intestine have been detected in brain and with lower abundance in many other tissues. It is not clear whether these transcripts code for rBAT or for a homologous protein. However, in these tissues, antibodies directed against rBAT react with structures located intracellularly rather than in the plasma membrane. As rBAT immunoreactivity has been localized to neurons that also express the neuronal isoform of NOS (NOS I), a role of rBAT in providing substrate for NOS I has been postulated (Pickel *et al.*, 1999). However, there are no functional data available to support this hypothesis. It would be interesting to establish whether there is an impairment of NOS I activity in patients with cystinuria as a result of restricted substrate availability.

In contrast to rBAT, 4F2hc is expressed in many cell types, including NO-producing cells. Like CAT-1, expression of 4F2hc is increased in proliferating cells and activated T cells (see review by Parmacek *et al.*, 1989). In addition to amino acid transport, a role of 4F2hc in other processes such as cell fusion and aggregation as well as cell survival has been postulated (see review by Palacin *et al.*, 1998). As the function of 4F2hc as an amino acid transporter is determined by its associated carrier, the identification of the respective light chain can provide the only insight into which transport system it might form in a given cell. In order to transport CAA, 4F2hc has to couple to y⁺LAT-1 or y⁺LAT-2 (to form system y⁺L), or to 4F2-lc6 (to form system b^{0,+}). y⁺LAT-1 is preferentially expressed in the renal cortex but also in small peripheral blood mononuclear cells, intestine, lung, and to a lesser extent in liver, placenta, and spleen. 4F2hc/y⁺LAT-1 is assumed to serve preferentially as an export mechanism for CAA at the basolateral membrane of epithelial cells (see Fig. 5). Consistent with this hypothesis is the basolateral localization of 4F2hc in renal epithelial cells and the involvement of y⁺LAT-1 mutations in LPI. The role of 4F2hc/y⁺LAT-1 or 4F2hc/y⁺LAT-2 in nonepithelial, for example, NO-producing cells, is not yet understood. The investigation

of NO synthesis in cells from LPI patients should shed light on whether 4F2hc/y⁺LAT-1 is important for providing substrate for NOS enzymes in specific cell types. 4F2-lc6 is predominantly expressed in kidney and small intestine and it has been suggested that it might be a new candidate gene for cystinuria (Rajan *et al.*, 1999). However, the subcellular localization of 4F2hc/4F2-lc6 in epithelial cells has not yet been investigated.

ATB^{0,+}

A cDNA encoding a Na⁺- and Cl⁻-dependent carrier (ATB^{0,+}) capable of transporting CAA has been isolated on the basis of sequence homology with neurotransmitter transporters (Sloan and Mager, 1999). ATB^{0,+} also mediates the Na⁺/Cl⁻-dependent transport of NAA with broad substrate specificity and exhibits high affinity for both CAA and NAA. ATB^{0,+} belongs to the family of Na⁺ and Cl⁻-dependent neurotransmitter transporters, including the transporter for betaine, taurine, serotonin, dopamine, glycine, and proline. Like all members of the family, it is predicted to span the membrane 12 times (see Fig. 3). ATB^{0,+} contains multiple consensus sites for N-linked glycosylation. Its expression is most abundant in lung and salivary gland, but it can also be found in mammary gland, stomach, and pituitary gland (Sloan and Mager, 1999). As CAA transport in NO-producing cells is mostly Na⁺-independent, ATB^{0,+} is not likely to play an important role in modulating substrate supply for NOS enzymes.

Conclusions

Mammalian cells are able to exchange cationic amino acids with the environment, and hence inhibition of CAA transport processes by competitor substrates may well affect intracellular metabolism of CAA, such as synthesis of NO. As L-arginine shares the same carrier proteins with other CAA, changes in carrier expression and/or activity will affect the transport of not only L-arginine and other CAA such as L-lysine and L-ornithine, but also cationic L-arginine analogs, including the naturally occurring symmetrical and asymmetrical dimethyl-L-arginine and some NOS inhibitors. Even substrates that have no direct effect on the activity of NOS may influence NOS activity in intact cells by competing with L-arginine for the same carrier proteins and changing the intracellular L-arginine concentration. Thus, the design of L-arginine analogs, targeted to individual CAA carrier proteins, could be exploited to specifically inhibit NOS in a given cell type where the respective carrier protein is crucial for the substrate supply for NO synthesis, without affecting the activity of NOS in other cell types. System y⁺ seems to be the major transport agency for L-arginine in NO-producing cells, and the carrier proteins mediating system y⁺ activity (CAT-1, -2B, and -3) are differentially expressed in these cells. Hence, the CAT proteins seem to be good candidates for the manipulation of substrate supply for NOS.

However, the involvement of other specific CAA carrier systems (b^+ , y^+L , $b^{0,+}$, $B^{0,+}$) in providing the substrate for NOS remains to be elucidated. Furthermore, as our understanding of the role that amino acid metabolism plays in modulating intracellular availability of L-arginine is limited, future research could investigate the potential of reversibly inhibiting intracellular pathways involved in metabolism of L-arginine.

Advances in our molecular understanding of amino acid transporters have provided important insights into the potential mechanisms regulating CAA transport in mammalian cells (see reviews by Closs, 1996, MacLeod, 1996, Deves and Boyd, 1998, Palacin *et al.*, 1998, and Closs and Gräf, 1999). Knockout experiments aimed at suppressing the expression of individual carrier isoforms or the development of selective pharmacological inhibitors will prove invaluable in determining the physiological relevance of specific CAA carrier proteins in regulating NOS activity in cells capable of releasing NO basically or in response to inflammatory stimuli.

The Respiratory Cycle: A Three-Gas System

Timothy J. McMahon, Andrew J. Gow, and Jonathan S. Stamler

*Howard Hughes Medical Institute and Department of Medicine
Duke University Medical Center
Durham, North Carolina*

THE BIOLOGY OF NITRIC OXIDE (NO) HAS BEEN DEFINED BY THE INTERACTIONS OF NO WITH HEMOGLOBIN (Hb). SPECIFICALLY, THE “ADDITION REACTION” IN WHICH NO PURPORTEDLY BINDS IRREVERSIBLY TO UNLIGANDED HEMES IN Hb, AND THE “OXIDATION REACTION” IN WHICH NITRATE AND METHEMOGLOBIN (metHb) ARE PRODUCED FROM THE INTERACTION OF NO WITH OXYHEMOGLOBIN (oxyHb), HAVE BEEN WIDELY VIEWED AS THE PRINCIPAL FATES OF NO *IN VIVO*. THESE REACTION PATHWAYS, HOWEVER, ARE DIFFICULT TO RECONCILE WITH THE ACTIVITY OF NO AS ENDOTHELIUM-DERIVED RELAXING FACTOR AND, IF DOMINANT, DICTATE THAT NO CONSUMPTION WOULD FAR EXCEED NO PRODUCTION *IN VIVO*, IN VIOLATION OF A MASS-BALANCE CONSTRAINT. HERE WE REVIEW RECENT WORK FROM OUR LABORATORY SHOWING THAT, IN FACT, THE NO ADDITION AND OXIDATION REACTIONS, AS OPERATIONALLY DEFINED, ARE OF SECONDARY IMPORTANCE UNDER PHYSIOLOGICAL CONDITIONS. INSTEAD, Hb RECRUITS ALTERNATIVE REACTION PATHWAYS WITH NO THAT PRESERVE ITS BIOACTIVITY. IN PARTICULAR, REACTIONS THAT S-NITROSYLATE THE PROTEIN ARE FAVORED IN THE R (OR OXYGENATED) STRUCTURE. FOR EXAMPLE, THE OXYGENATION-INDUCED ALLOSTERIC TRANSITION IN Hb [FROM THE T (OR DEOXYGENATED) TO THE R STRUCTURE] IN THE LUNG TRIGGERS THE MIGRATION OF NO FROM HEMES TO CYS- β 93, THEREBY FORMING S-NITROSOHEMOGLOBIN (SNO-Hb). CONVERSELY, THE DEOXYGENATION-LINKED ALLOSTERIC TRANSITION IN SNO-Hb (FROM THE R TO THE T STRUCTURE) PROMOTES THE RELEASE OF NO BIOACTIVITY IN THE TISSUES TO AUGMENT BLOOD FLOW. BECAUSE O₂ AFFINITY IS INCREASED IN SNO-Hb, S-NITROSYLATION HAS THE EFFECT OF LIMITING THE EXCESSIVE OR UNTIMELY RELEASE OF NO GROUPS. THESE DATA SHOW THAT Hb CONSERVES ITS NO WHILE DISPENSING IT SELECTIVELY TO MAXIMIZE O₂ DELIVERY IN THE RESPIRATORY CYCLE.

Introduction

The chemistry of nitric oxide (NO) interactions with hemoglobin (Hb) has been critical to our understanding of NO biology. The landmark identification of NO bioactivity with endothelium-derived relaxing factor (EDRF), for example, relied in part on observations that NO and EDRF were each seemingly inactivated by Hb (Ignarro *et al.*, 1987; Palmer *et*

al., 1987). Similarly, NO biology in the specific realm of the cardiovascular system has been predicated on two classic tenets: (1) NO binding to unliganded (deoxygenated) hemes in Hb is noncooperative and effectively irreversible [the NO addition reaction; Eq. (1)], and (2) that NO reaction with oxyhemoglobin (oxyHb) yields methemoglobin (metHb) and nitrate [the NO oxidation reaction; Eq. (2)] (Eich *et al.*, 1996; Gow *et al.*, 1999; Gross and Lane, 1999).

These reactions with hemoglobin have been viewed both as a way of mitigating NO vasoactivity and as a route of NO elimination from the body. However, assuming these reactions to be the principal fate of endothelium-derived NO, the amount of NO synthesized daily is calculated to be several orders of magnitude too low to sustain the level of NO bioactivity that is required to dilate blood vessels (Castillo *et al.*, 1996; Gow *et al.*, 1999). Thus, biological models built on these assumptions not only are unable to explain how EDRF can dilate blood vessels *in vivo*, when Hb scavenges NO and constricts blood vessels *in vitro*, but also present what we have termed a mass-balance constraint: NO consumption would far exceed production. Gross and Lane (1999) have eluded to the additional problem that tissue oxygenation would be compromised by the inexorable accumulation of iron nitrosylHb (Hb[Fe(II)]NO) and metHb, were additional reaction pathways not available for NO.

The major failings of the classic model are twofold. First, whereas EDRF was originally identified with free NO, we have come to understand that a significant component of EDRF-related activity exists in the form of S-nitrosothiols (SNOs) (Creager *et al.*, 1997; Day *et al.*, 1996; Lancaster, 1994; Stamler, 1996), which are not subject to inactivation by hemoglobin (Gaston *et al.*, 1994; Jia *et al.*, 1996). Second, it is now clear that alternative NO reaction pathways with Hb are available, which preserve its bioactivity (Gow *et al.*, 1999; Gow and Stamler, 1998). These reaction channels serve two functions: they recycle NO (to obviate the mass-balance constraint) (Gow and Stamler, 1998; Gross and Lane, 1999), and they dispense it for regulation of O₂ delivery in the respiratory cycle (Gross and Lane, 1999; Stamler *et al.*, 1997). More specifically, Hb assumes the R conformation in O₂-rich environments, enabling NO to bind cooperatively to vacant hemes [Eq. (3)]. Additional S-nitrosylation pathways are then available to secure NO groups [Eq. (4), see discussion], which are thereby transported to the tissues. There, S-nitrosohemoglobin (SNO-Hb) undergoes an O₂-linked allosteric transition from the R to the T structure that triggers the delivery of vasodilator SNOs. In this revised picture SNO-Hb is the principal NO reservoir in the circulation, functioning as an allosterically controlled NO buffer, dispensing NO groups to tissues in need (Jia *et al.*, 1996; Stamler *et al.*, 1997). SNO-Hb does not transition to the T structure, however, if tissue PO₂ rises (as in O₂ delivery exceeding tissue demand). The net result in this case is NO sequestration [Eq. (3)] and consequently vasoconstriction. Accordingly, SNO-Hb participates in the classic physiological responses of hypoxic vasodilation and hyperoxic vasoconstriction.

Oxygen affinity is greater in SNO-Hb than in unmodified Hb (Bonaventura *et al.*, 1999; McMahon *et al.*, 2000; Patel *et al.*, 1999; Wolzt *et al.*, 1999). Given that the fraction of Hb molecules carrying SNO is $\sim 1/1000$, this augmented O₂ affinity is, however, unlikely to influence the aggregate O₂ affinity of blood. Rather, evidence suggests that by shifting the equilibrium toward the R structure, S-nitrosylation serves to limit the excessive release of NO groups from SNO-Hb (McMahon *et al.*, 2000). Here we review the results of experiments that show how SNO-Hb senses hypoxia to regulate blood flow and hence O₂ delivery within the respiratory cycle, and yet tightly controls what would otherwise be a deleterious, untimely, or excessive release of vasodilator (S)NO. In other words, Hb conserves the vast majority of its NO.

Nitric Oxide Reactions with Hemoglobin, and Allosterically Related Bioactivity: Selected Methods and Results

The Oxyhemoglobin and NO Addition Reactions

Difference absorption spectroscopy was used to assess the formation of metHb and nitrosylHb on the addition of NO to Hb under aerobic conditions (Gow *et al.*, 1999). Standard difference spectra of authentic metHb, deoxyhemoglobin (deoxyHb), and iron nitrosylHb versus oxyHb are shown in Fig. 1A. Submicromolar concentrations of NO were titrated against 33 μM Hb in room air (O₂ saturation, 99%), and the difference spectra versus oxyHb are shown in Fig. 1B. Assuming a model of simple competition between the production of nitrosylHb (the addition reaction) and that of metHb (the oxyhemoglobin reaction), the expected difference spectrum at 99% O₂ saturation under these conditions would largely resemble that of metHb. Instead, however, the difference spectra primarily show the formation of nitrosylHb (i.e., the difference spectrum can be mostly accounted for by the deoxyHb minus oxyHb standard spectrum, Fig. 1A). Furthermore, photolysis–chemiluminescence analysis of the reaction products under similar conditions reveals yields of SNO-Hb exceeding those of Hb[Fe(II)]NO (Fig. 1C). Thus, under physiological conditions (and, in particular, when the NO to heme ratio is $< 1/100$), the direct oxidation of oxyHb by NO does not predominate. Rather, NO binding to the unliganded hemes in oxyHb is cooperative, and Hb recruits additional reaction pathways, including S-nitrosylation, in order to preserve NO.

Auto S-Nitrosylation of Hemoglobin on Oxygenation

The yield of SNO was measured in partially nitrosylated hemoglobin solutions following rapid exposure to air (which induces the allosteric transition from the T to the R conformation) (Gow and Stamler, 1998). When ratios of NO to Hb were in the physiological range (1:100 or less), intramolecular NO group transfer from heme to thiol accounted for

Figure 1 The oxyhemoglobin reaction of NO does not account for its fate under physiological conditions. (A) Difference spectra for standard solutions of methHb (solid line), deoxyHb (dotted line), and nitrosylHb (dashed line) versus oxyHb. (B) Difference spectra generated from the exposure of NO to normoxic ($\sim 99\%$ O_2 saturated) Hb. NO was added to Hb in 100 mM phosphate (solid line), 10 mM phosphate (dotted line), or 10 mM phosphate plus 0.05% borate. NitrosylHb and some methHb forms in 10 mM phosphate (conditions which favor the R structure); mainly nitrosylHb forms in the added presence of borate; whereas mainly methHb is formed in 100 mM phosphate (which favors the T structure among the partially liganded molecules). (C) SNO-Hb and Hb[Fe(II)]NO formed by exposure of oxygenated Hb ($\sim 99\%$ saturation, $48 \mu M$) to NO ($1.2 \mu M$). SNO (open bar) and Fe(II)NO (solid bar) were measured by photolysis-chemiluminescence (Jia *et al.*, 1996; Stamler *et al.*, 1997). Data shown are the average of 12 experiments \pm standard error.

$\sim 80\%$ of the initial NO added (Fig. 2). These findings indicate that Hb itself promotes the formation of SNO. Molecular O_2 in this context serves both to trigger the conformational change in Hb and to accept an electron in the S-nitrosylation reaction (Gow *et al.*, 1997). As the NO:Hb ratio is raised, however, the SNO yield drops to near zero (i.e., NO becomes increasingly unavailable to form SNO, Fig. 2). SNO formation increases again at higher ratios of NO:Hb (1:1 and greater) but reaches a maximum of $\sim 5\%$ of

Figure 2 Auto S-nitrosylation of Hb. Varying amounts of NO were added to deoxyHb, the mixture was immediately oxygenated by rapid exposure to air, and the yield of S-nitrosothiol was measured. SNO yield is expressed both in absolute terms (μM) and relative to the initial NO added. The means \pm SEM of 4–27 experiments are shown.

the NO added; this reaction is not likely to have physiological relevance (Fig. 2).

Hemoglobin-Bound NO in Mammalian Blood

The allosteric regulation of the distribution of NO binding sites was studied in rat blood (Stamler *et al.*, 1997). SNO-Hb and Hb[Fe(II)]NO levels were measured before and during elimination of the longitudinal O_2 gradient (the difference in O_2 saturation from artery to arteriole and from artery to vein) in hyperbaric chambers by the application of 3 ATA (atmospheres of absolute pressure) and the administration of 100% O_2 . Hb[Fe(II)]NO predominated in venous blood from rats breathing 21% O_2 , whereas SNO-Hb was present in significant amounts in arterial blood drawn simultaneously (Fig. 3). When the O_2 gradient was then eliminated in these rats (i.e., arterial and venous blood were 100 and 93% O_2 saturated, respectively), SNO-Hb was the predominant Hb–NO adduct in both arterial and venous blood (Fig. 3). Thus, SNO-Hb appears to form endogenously in the R

Figure 3 Hb-bound NO in mammalian blood: role of O_2 tension. SNO-Hb and Hb[Fe(II)]NO levels in arterial and venous blood were measured in rats exposed first to room air (RA) at 1 atmosphere (ATA) and then to 100% O_2 and 3 ATA. O_2 saturations were as follows: venous/RA, 69%; arterial/RA, 93%; venous/100% O_2 + 3 ATA, 93%; arterial/100% O_2 + 3 ATA, 100%.

structure, whereas the release of SNO *in vivo* is favored in the T structure. Remarkably, total levels of Hb-bound NO appear to remain relatively constant from artery to vein in both the presence and absence of an O₂ gradient. Thus, at least some of the (S)NO released when Hb undergoes the allosteric transition appears to be autocaptured at the hemes, preserving NO signaling equivalents.

O₂ Affinity of S-Nitrosohemoglobin

The O₂ affinities of Hb and SNO-Hb (~1.8 SNO per Hb tetramer) were compared using standard tonometric techniques (McMahon *et al.*, 2000). The O₂ binding curve, expressed as a Hill plot, for SNO-Hb was shifted to the left relative to that of unmodified Hb (Fig. 4). The leftward shift was asymmetric in that differences in affinity between Hb and SNO-Hb were greatest at low PO₂ values (Fig. 4). These results suggest that the increased O₂ affinity in SNO-Hb is largely attributable to a destabilization of the T structure. Reciprocal relationships between the binding of O₂ and NO to hemes and thiols, respectively, required by thermodynamics (Wyman, 1964), thus dictate that deoxygenation promotes NO group release from thiols.

S-Nitrosohemoglobin Vasoactivity: Allosteric Control and Potentiation by Low-Mass Thiols

The influence of the oxygen tension and thiol abundance on the bioactivity of SNO-Hb was studied in vascular ring bioassays (McMahon *et al.*, 2000). Rings of rabbit thoracic aorta were mounted in tissue baths filled with Krebs buffer solution and bubbled with varied gas mixtures. In 21% O₂, vessel rings incubated with glutathione (GSH) at either 10⁻⁷ or 10⁻⁵ M contracted in response to SNO-Hb (Fig. 5) in a concentration-dependent manner. These responses are consistent with the sequestration of endothelium-derived NO

Figure 4 O₂ affinity is increased in SNO-Hb. The O₂-binding curves for Hb and partially S-nitrosylated Hb (SNO/Hb tetramer ratio ~1.4) were compared using a standard tonometric technique and are expressed as Hill plots (the $\log[Y/(1 - Y)]$ versus $\log pO_2$, where Y is the fractional O₂ saturation). The leftward shift for SNO-Hb is asymmetric in that differences are greatest at low PO₂ values.

and are comparable to responses to unmodified Hb (data not shown). In the presence of 10⁻³ M GSH, however, vasorelaxation was seen in response to SNO-Hb. In hypoxia (<1% O₂), SNO-Hb elicited vasorelaxation in the presence of 10⁻⁵ M GSH; i.e., its potency was increased 100-fold (Fig. 5). Thus, SNO-Hb bioactivity is linked to the allosteric transition in Hb: in the R structure, responses primarily reflect scavenging at the heme centers, whereas in the T structure, (S)NO group release and vasorelaxation are facilitated. The low-molecular-weight thiol GSH accelerates the release of (S)NO from SNO-Hb *in vitro*, in keeping with Eqs. (4) and (5).

Blood Flow Regulation by S-Nitrosohemoglobin: Allosteric Control

Anesthetized adult rats were intubated and mechanically ventilated so as to maintain a PCO₂ of 35–45 mm Hg (Stamler *et al.*, 1997). The inspired O₂ concentration and the atmospheric pressure were adjusted in order to change the arterial PO₂. Regional blood flow was measured using H₂-sensitive platinum microelectrodes implanted in various regions in the brain. Changes in local blood flow in response to intravenous Hb or SNO-Hb (1 μmol/kg i.v. over 3 min) were compared (Stamler *et al.*, 1997). Hb reduced blood

Figure 5 Control of SNO-Hb vasoactivity by the allosteric state and thiol abundance. Isometric changes in tension in response to SNO-Hb were measured in isolated rabbit aortic rings in either 21% O₂ (A) or <1% O₂ (B) and in the presence of varying concentrations of GSH (10⁻⁷, 10⁻⁵, or 10⁻³ M).

Figure 6 Regulation of blood flow *in vivo* by S-nitrosohemoglobin. Changes in blood flow following the administration of either Hb or SNO-Hb were measured in the cerebral cortex of rats either when breathing 21% O₂ at 1 ATA (A) or when the physiological O₂ gradient was eliminated by the administration of 100% O₂ and the application of 3 ATA (B). **p* < 0.05 by ANOVA for SNO-Hb versus Hb (*n* = 7).

flow, whereas SNO-Hb raised blood flow in rats breathing 21% O₂ (normoxia, Fig. 6A). In contrast, decreases in blood flow were seen in response to both Hb and SNO-Hb when the physiological O₂ gradient was eliminated by the administration of 100% O₂ in hyperbaric chambers adjusted to 3 ATA (Fig. 6B).

Discussion

Our understanding of NO biology has been shaped by the viewpoint that hemoglobin eliminates NO bioactivity by oxidizing it to nitrate [Eq. (2)]. Previous studies, however, had been carried out with NO concentrations in excess of Hb (Eich *et al.*, 1996), whereas the NO concentration *in vivo* is only a fraction of the Hb (0.01%). Moreover, the population of vacant hemes in oxygenated blood (typically 1% of total Hb is desaturated) always exceeds that of free NO. This excess, together with the cooperativity of NO binding to oxyHb, enables the binding of NO to outcompete the oxidative pathway [Eq. (2)] even (indeed, especially) at high O₂ saturations [Eq. (3)] (Gow *et al.*, 1999). NO bound to hemes in oxygenated Hb is oxidatively transferred to Cys-β93, thereby preserving NO bioactivity in the form of SNO-Hb (Gow *et al.*, 1999; Gow and Stamler, 1998; Jia *et al.*, 1996) [Eq. (4)]. Such S-nitrosylated proteins exist in equilibrium with peptide and amino acid SNOs in all biological systems [Eq. (5)] (Gaston *et al.*, 1998; Jia *et al.*, 1996). NO channeling through interactions with Hb thus provides a means to account for the equilibrium population of SNOs in blood, which constitute the vast majority of NO bioactivity *in vivo* (Jia *et al.*, 1996; Stamler *et al.*, 1992, 1997).

More generally, our data speak to the existence of a redox-dependent equilibrium between NO groups bound to hemes of Hb in the T structure and thiols of Hb in the R structure [Eq. (7)]. Accordingly, the oxygenation-induced allosteric transition of partially nitrosylated Hb molecules is reciprocally coupled with NO migration from hemes (of T structure molecules) to Cys-β93 (in the R structure) (Gow and Stamler, 1998; McMahon *et al.*, 2000). In other words, SNO-Hb is also formed when partially nitrosylated Hb is exposed to O₂, as in the case of red blood cells entering the lung. Conversely, deoxygenation promotes NO group release from Cys-β93, as happens during arterial-venous transit (Jia *et al.*, 1996; McMahon *et al.*, 2000; Stamler *et al.*, 1997). It is important to recognize that molecular O₂ not only is involved in triggering the allosteric transition—a function that might be alternatively carried out by other allosteric effectors (PCO₂ and pH) and which determines the equilibrium position in Eq. (7)—but is also capable of serving as an electron acceptor in the synthesis of SNO (Gross and Lane, 1999).

The binding and release of NO groups by the highly conserved Cys-β93 of Hb are controlled not only by the allosteric state of Hb but also by the abundance of ambient thiols capable of transducing the SNO signal [Eq. (5)]. Such transnitrosation reactions are likewise promoted by deoxygenation and heme oxidation (T structure, high spin) (Jia *et al.*, 1996; Pawloski *et al.*, 1998; Stamler *et al.*, 1997), in keeping with thermodynamic linkage relationships in Hb (Wyman, 1964). For example, SNO-Hb is also in equilibrium with low-mass SNOs (Ignarro *et al.*, 1987), such as S-nitrosoglutathione (GSNO) [Eq. (5)]. High concentrations of GSH thus shift the equilibrium in favor of the deoxy structure (Jia *et al.*, 1996) [Eq. (5) and (6)]. As is generally the case for SNOs, the mechanism of vasorelaxation by GSNO is independent of free NO (Gaston *et al.*, 1998; Kerr *et al.*, 1992), which would only be sequestered at the hemes of Hb.

Our findings motivate a revision of the respiratory cycle, which can now be viewed as a “three-gas system” (in which Hb transports NO, CO₂ and O₂) (Gross and Lane, 1999). In relatively deoxygenated central venous blood, Hb binds NO primarily at the hemes (Fig. 7). As Hb takes up oxygen in the lung, SNO-Hb is formed (in concert with the conformational switch from the T to the R structure in NO-carrying Hb molecules). The NO group is subsequently released from SNO-Hb in the peripheral microcirculation where PO₂ is low. Transnitrosation reactions with ambient thiols are implicated in the dilation of blood vessels and thereby couple regional blood flow with the metabolic needs of the tissues. However, not all of the NO/SNO released from Hb reaches targets in vascular smooth muscle. Rather, some NO is also

Figure 7 Transport and delivery of NO groups by Hb within the respiratory cycle.

recaptured at the hemes. In this way, Hb conserves its NO (Funai *et al.*, 1997; Gladwin *et al.*, 1999; Jia *et al.*, 1996; McMahon *et al.*, 2000).

This preservation of NO bioactivity and tight control of seemingly small concentrations of NO can be understood by appreciating a fundamental difference between NO and O₂ in biology: (S)NO acts principally as a signal at nanomolar concentrations (De Belder *et al.*, 1994; Feelisch *et al.*, 1994; MacAllister *et al.*, 1995), whereas O₂ supports aerobic metabolic activities at millimolar concentrations. Accordingly, the liberation of only a small fraction (<0.1%) of the micromolar concentrations of Hb-bound SNO across the peripheral microcirculation is sufficient to evoke substantial regional increases in blood flow. Moreover, release of larger amounts would not be compatible with life on two accounts. First, it would impose a metabolic burden on the organism: more NO would be turned over by Hb than is produced within the lining of the blood vessels. Second, release of micromolar SNO would cause hypotension and shunting of blood. Multiple mechanisms, in fact, operate *in vivo* to limit the flux of NO/SNO released from Hb. These include the autocapture of NO by the hemes of Hb (Ignarro *et al.*, 1987; McMahon *et al.*, 2000) and the augmented intrinsic O₂ affinity of SNO-Hb, which disfavors the deoxygenation-dependent release of SNO. By reinforcing the R structure in Hb (see Hill plots in Fig. 4), S-nitrosylation mitigates the untimely or excessive offloading of NO, which would be incompatible with life.

How NO-Hb interactions may regulate or perturb blood flow in pathophysiological settings is less clear. Hb[Fe(II)]NO levels are high in animal models of endotoxic (lipopolysaccharide-induced) sepsis (Kosaka *et al.*, 1997). In these experiments, NO was found to bind primarily to the α -hemes, shifting the aggregate O₂-binding curve slightly to the right (Kosaka *et al.*, 1997). It is unclear, however, that NO ever reaches sufficient concentrations to have meaningful effects on O₂ delivery through direct posttranslational effects on the protein. Indeed, the importance of NO binding to Hb lies not in its effect on the population of Hb at large, but on the functional behavior of the few molecules carrying NO. That is, NO binding to thiols of Hb limits the release of NO groups on deoxygenation of (S)NO-carrying molecules by shifting the equilibrium position in Eq. (5) to the left. In this way Hb tightly regulates the dispensing of NO groups. Because blood flow is regulated by nanomolar SNO targeted toward smooth muscle (Feelisch *et al.*, 1994; Jia *et al.*,

1996; MacAllister *et al.*, 1995), this tight regulation of the NO group is far more important for O₂ delivery than any NO-related change in O₂ saturation of Hb, which could only be effected by supraphysiological NO levels. The formation of five-coordinate α -nitrosyls in Hb is particularly well adapted to this end, as they serve to reinforce the T structure in Hb (Gow and Stamler, 1998; Yonetani *et al.*, 1998). Inasmuch as high concentrations of NO and low pH favor five-coordinate α -nitrosyls in Hb, this scenario may present a means to raise blood pressure in the septic animal. We are currently investigating Hb-bound NO dynamics in human sepsis.

Our findings have important implications for the development of experimental therapeutics designed to exploit NO-Hb interactions *in vivo*. For example, inhaled NO or alternative NO donor agents—once believed to be inactivated by erythrocytic Hb—might be administered for extrapulmonary effects (Fox-Robichard *et al.*, 1998; Kermarrec *et al.*, 1998; Kubes *et al.*, 1999; Troncy *et al.*, 1997), and thus may be utilized in the treatment of ischemic diatheses (e.g., angina, stroke, or sickle cell disease). Moreover, by regulating the NO channeling in Hb, one might anticipate both the promise of improved NO delivery functions by hemoglobins as well as the ability to divert NO toward storage pools or detoxification pathways that may ameliorate the undesirable effects of blood substitutes or the NO overproduction in septic shock.

New York, New York*

FREE RADICALS DERIVED FROM NITROGEN AND OXYGEN HAVE BEEN FOUND TO HAVE A SIGNIFICANT ROLE IN PHYSIOLOGICAL AND PATHOPHYSIOLOGICAL PROCESSES. ORIGINALLY, FREE RADICALS WERE BELIEVED TO BE ASSOCIATED EXCLUSIVELY WITH CELLULAR DAMAGE. FREE RADICALS ARE NOW WIDELY IMPLICATED IN CELLULAR SIGNALING, A FACT WHICH ATTACKS OUR CLASSIC NOTION OF BIOLOGICAL MEDIATORS UTILIZING RECEPTOR–LIGAND INTERACTIONS IN A “LOCK AND KEY” MANNER. FREE RADICAL SIGNALING IS MAINLY BASED ON REDOX CHEMISTRY, A UNIQUE MODE OF SIGNAL TRANSDUCTION. NITRIC OXIDE (NO), WHICH IS SYNTHESIZED IN MOST TISSUES, IS DIFFUSIBLE AND CAN TAKE ON SEVERAL CHEMICAL FORMS, EACH OF WHICH HAS ITS OWN REACTIVE SPECIFICITY. THE MAJOR CHEMICAL MODIFICATION PRODUCED BY THESE SPECIES IS NITROSATION OF THE TARGET, GENERALLY A PROTEIN IRON OR THIOL. THE DIRECT INTERACTION OF NITRIC OXIDE WITH THE PROTEIN TARGET MAY RESULT IN EITHER ACTIVATION, INACTIVATION, OR SWITCHING OF PROTEIN FUNCTION AND SUBSEQUENT MODULATION OF GENE EXPRESSION. SOME PHYSIOLOGICAL EVENTS REGULATED BY THIS TYPE OF SIGNALING INCLUDE VASODILATION, CYTOTOXICITY, INFLAMMATION, AND SYNAPTIC PLASTICITY. REACTIVE OXYGEN SPECIES AID IN PROPAGATING SIGNALS TRIGGERED BY GROWTH FACTORS, HORMONES, AND CYTOKINES. THESE SPECIES ALSO MODIFY THE TARGETS DIRECTLY. SOME OF THE PHYSIOLOGICAL EVENTS REGULATED BY REACTIVE OXYGEN SPECIES INCLUDE CELL GROWTH, CELL ADHESION, APOPTOSIS, ION TRANSPORT, NEUROMODULATION, AND TRANSCRIPTION. THIS CHAPTER ATTEMPTS TO EXPLAIN THE MECHANISTIC BASIS OF CELL SIGNALING BY NITROGEN- AND OXYGEN-DERIVED CHEMICAL SPECIES AND DISCUSSES THEIR CELLULAR TARGETS AND THE PHYSIOLOGICAL EVENTS THEY REGULATE.

Introduction

Multicellular organisms function in an organized manner by communicating within and between various organs and tissues. Cells communicate by using different kinds of signaling molecules such as proteins, small peptides, amino acids, nucleotides, steroids, retinoids, fatty acid derivatives, and gases such as nitric oxide (NO). Cells respond to this apparent babel of signals in an organized manner either by

differentiating, by proliferating, by dying, or by performing some specialized function.

Depending on the type of signal, the target cell initiates a specific signaling cascade. This specificity is achieved by means of cellular receptors that are either on the cell surface or inside the target cell. Transmembrane receptors on the cell surface are essential for hydrophilic signaling molecules that cannot cross the lipid bilayer. The activated receptor transmits a signal across the membrane and generates an intracel-

lular messenger. Hydrophobic compounds, such as steroid hormones, can pass through the plasma membrane, bind to specific intracellular receptors, and directly trigger gene transcription. Steroid hormones do not need any intervening signal transducers. Similarly, gaseous signaling molecules can also bypass surface receptors by diffusing through the target cell plasma membrane. Here we focus on how free radical species transmit signals. In order to appreciate the signaling mechanisms utilized by gaseous messengers like nitric oxide and reactive oxygen species, it is necessary to take an overview of classic cell signaling (Alberts *et al.*, 1994; Hardie, 1990).

How Is Classic Signal Transduction Achieved?

Because steroid hormones can permeate cells easily and bind to intracellular receptors that directly regulate gene ex-

pression, they do not generate many signaling events in the cell (Fig. 1). However, hydrophilic signaling molecules generate many molecular signaling events on interaction with surface receptors. Most cell surface receptors belong to one of three classes, depending on the transduction mechanism used: ion channel-linked receptors, G protein-linked receptors, and enzyme-linked receptors.

Ion Channel-Linked Receptors

Ion channel-linked receptors are mainly involved in inorganic ion transport. They specifically allow Na^+ , K^+ , Ca^{2+} , or Cl^- to diffuse through the lipid bilayer. Specificity of ion transport is achieved through size and charge selection by the channel. Gates of ion channels are regulated by either voltage potential across the membrane, mechanical stress, or a ligand binding to its receptor.

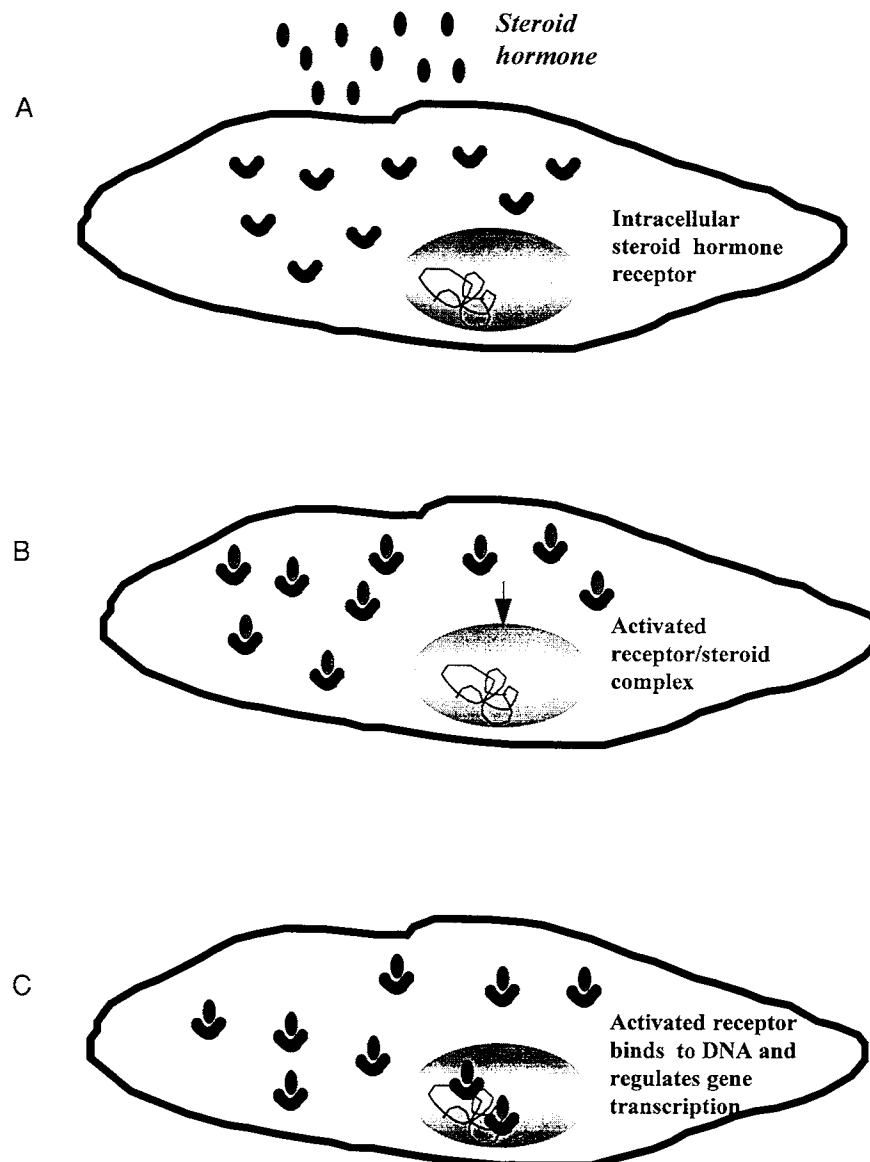

Figure 1 Interaction of steroid hormone with its intracellular receptor.

In the nervous system, neurotransmitters mediate signaling by ion channels. Acetylcholine released by nerve terminals binds to its receptors on the muscle cell plasma membrane, which triggers opening of the gated cation channels associated with it. This leads to a large influx of Na^+ , resulting in membrane depolarization. As a result of local depolarization, more Na^+ enters due to opening of voltage-gated Na^+ channels, and the local depolarization spreads through the entire plasma membrane. This activates the voltage-gated Ca^{2+} channels of the muscle cell and finally opens the Ca^{2+} release channels of the sarcoplasmic reticulum. The Ca^{2+} released from the sarcoplasmic reticulum contracts the myofibrils of the muscle cell. Thus, the signaling cascade triggered by acetylcholine brings about a functional response in the target cell, namely, muscle contraction (Fig. 2).

G Protein-Linked Receptors

The G protein-linked receptors indirectly relay signals either to enzymes or to ion channels via their associated trimeric GTP-binding proteins (G proteins). The receptors in this superfamily have similar secondary structures with a single polypeptide chain that threads the lipid bilayer seven times. The G proteins associated with the receptors are known to conduct a variety of signals by hormones, neurotransmitters, and growth factors. G proteins do not signal when bound to GDP and trigger signaling when bound to

GTP. Ligand binding to these receptors triggers GDP/GTP exchange on the associated G protein. This, in turn, activates a chain of intracellular events leading to alteration in second messenger levels (Fig. 3). For example, epinephrine, a stress hormone released by the adrenal gland, binds to its G protein-linked receptor and relays a signal via cyclic AMP. During stress, one of the messages conveyed by epinephrine is to mobilize glucose. It binds to the β -adrenergic receptors on muscle cells and activates a G protein and adenylyl cyclase. This in turn increases the level of cyclic AMP, which then activates cyclic AMP-dependent protein kinase. This enzyme phosphorylates two other enzymes: phosphorylase kinase and glycogen synthase. Phosphorylase kinase further phosphorylates glycogen phosphorylase and helps in releasing glucose by breaking down glycogen. Also, phosphorylation of glycogen synthase inhibits its activity and thus prevents glycogen synthesis. By this signaling pathway epinephrine makes glucose available in order to respond to stress.

Calcium ion is an important second messenger and is involved in signaling that leads to muscle contraction, neurotransmission, gene transcription, and cell growth. A Ca^{2+} gradient exists across the cell because the Ca^{2+} concentration of the cytosol is kept extremely low ($10^{-7} M$) as compared to cell exterior ($10^{-3} M$) and the endoplasmic reticulum. A stimulus increases the Ca^{2+} concentration in the cytosol by activating a Ca^{2+} channel either in the plasma membrane or in the endoplasmic reticulum. The increase in cytosolic Ca^{2+} subsequently activates Ca^{2+} -responsive proteins in the cell. These include troponin, some members of the protein kinase C family, Ca^{2+} -calmodulin kinases, calmodulin-dependent protein phosphatase, and nitric oxide synthase.

The receptors of ligands such as vasopressin, acetylcholine, and thrombin activate a G protein which modulates Ca^{2+} levels of the cytosol. Initially, GTP-bound G protein activates phospholipase C- β . This enzyme acts on phosphorylated phosphatidylinositol, a phospholipid present in the cell membrane. It generates two products, inositol trisphosphate and diacylglycerol. Inositol trisphosphate opens Ca^{2+} release channels on the endoplasmic reticulum and releases Ca^{2+} into the cytosol. Increased Ca^{2+} levels further regulate Ca^{2+} -responsive proteins. Diacylglycerol is cleaved into arachidonic acid, or it may directly activate various members of the protein kinase C family. Protein kinase C specifically phosphorylates serine and threonine residues on target proteins, which include transcription factors and other regulatory proteins, ultimately regulating the transcription of specific genes.

Enzyme-Linked Receptors

Enzyme-linked receptors are transmembrane proteins with an extracellular ligand binding domain and a cytosolic domain which either has intrinsic enzyme activity or is associated with an enzyme. These receptors can be further classified into five categories on the basis of their enzymatic activities (Fig. 4).

Figure 2 Ion channel-linked receptor (e.g., neurotransmitters).

Figure 3 G-protein-linked receptors (e.g., epinephrine, vasopressin, thrombin).

RECEPTOR GUANYLYL CYCLASE

Guanylyl cyclase receptors directly convert GTP to cyclic GMP on ligand binding. Members of the atrial natriuretic peptide family utilize this mode of signaling.

RECEPTOR TYROSINE KINASES

Tyrosine kinase receptors auto- and *trans*-phosphorylate tyrosine residues on ligand binding. Ligands for these receptors include various growth factors such as epidermal growth factor, insulin, insulin-like growth factor, platelet-derived growth factor, nerve growth factor, and vascular endothelial growth factor.

TYROSINE KINASE-ASSOCIATED RECEPTOR

The tyrosine kinase-associated receptors mainly depend on associated nonreceptor tyrosine kinases for propagating the signal. This family includes receptors for cytokines, hormones, and antigen-specific receptors on T and B cell receptors. The associated nonreceptor tyrosine kinases mainly belong to either the Src or Janus family.

RECEPTOR TYROSINE PHOSPHATASE

Tyrosine phosphatase receptors propagate signals by removing phosphate groups from specific tyrosine residues of a particular protein. CD45 present on lymphocytes belongs to this receptor class.

RECEPTOR SERINE/THREONINE KINASES

Serine/threonine kinase receptors phosphorylate serine and threonine residues on target proteins. Receptors of the transforming growth factor β superfamily have this enzymatic property.

The receptors for most growth factors are transmembrane tyrosine protein kinases. Hence, the signaling cascade generated by this receptor class will be discussed briefly. Ligand–receptor interaction leads to autophosphorylation of the receptor on tyrosine. The phosphotyrosine residues serve as docking sites for intracellular signaling proteins including GTPase-activating proteins, phospholipase C- γ , and phosphatidylinositol 3'-kinase via their common SH2 domains.

Figure 4 Enzyme-linked receptors (e.g., growth factor, cytokine, and the T and B cell receptors).

This association sets in motion the signaling cascade. Some of the key signaling components include the monomeric G protein Ras, Raf kinase, and the mitogen-activated protein (MAP) kinases.

The above overview of classic signaling events helps one appreciate how the cell has evolved intricate and well-controlled means of communication in order to respond specifically to environmental cues. A novel means of communication has been identified whereby cells utilize reactive free radical species derived from nitric oxide and oxygen to propagate signals. Unlike conventional receptor–ligand signaling that involves lock and key recognition, the basis of free radical signaling is chemistry. Reactive free radical species interact with different targets such as thiols and iron, depending on their redox potential. However, a major conceptual hurdle in redox signaling is understanding the means by which specificity is achieved. Its involvement in various crucial cellular events such as ion transport, neuromodulation, apoptosis, gene transcription, and growth factor signaling leaves little doubt that redox signaling has evolved into a specific and major signaling mechanism. How simple chemical events regulate biological processes will be the focus of next sections.

Nitric Oxide:

How Does It Fit into Signal Transduction?

It Can Bypass Interactions at the Surface of the Cell

Nitric oxide can diffuse through cellular membranes with ease. Hence, a cell does not need a specific receptor to respond to nitric oxide signaling; rather, specificity of signaling is regulated at different levels. This is achieved by modulating the NO synthesis machinery, the redox milieu of the cell, the availability of protein binding sites, and the scavenger proteins that regulate the chemical form and effective concentration of NO. NO and its congeners signal via mechanisms used by both protein kinases, which control function by covalent modification (i.e., phosphorylation), and reactive oxygen species, which signal through redox events and coordinative interactions with metals.

Target Specificity Is Achieved through Chemistry

Through its interactions with intracellular or extracellular moieties, NO can be quickly scavenged or stabilized, or it can transiently modify cellular targets. Interestingly, the endogenous scavenger glutathione stabilizes and transports NO by forming adducts and converting itself into a NO donor. Depending on the redox milieu, NO can modify its target very quickly. The chemistry of NO plays a critical role in determining its cellular targets. NO has an unpaired electron, making it highly reactive, and its reaction with redox modulators yields many reactive species. Thus, the term NO does not reveal anything regarding its different redox forms. Hence, the term reactive nitrogen species (RNS) is used in this chapter to refer to those species whose origin is the free radical NO, but whose final chemical nature depends on its interaction with local redox modulators and the redox milieu of the cell (Lander, 1997).

NO can exist in three redox forms: nitrosonium cation (NO^+), nitric oxide ($\cdot\text{NO}$), and nitroxyl anion (NO^-) with nitrogen oxidation numbers +3, +2, and +1, respectively. In the presence of superoxide anion (O_2^-), NO combines to form peroxynitrite (OONO^-), a strong prooxidant species:

In aqueous aerobic solutions NO predominantly forms nitrite (NO_2^-). In the presence of oxyhemoglobin and oxymyoglobin, NO is completely oxidized to nitrate (NO_3^-) (Stamler *et al.*, 1992a; Ignarro *et al.*, 1993).

Covalent interactions of RNS with cellular macromolecules are responsible for its many physiological and pathological effects. Proteins containing iron and thiol groups are the major cellular targets of RNS. Extensive studies have been performed characterizing the RNS–iron interaction. The iron, as Fe^{2+} or Fe^{3+} , can be targeted when either in a heme group or in an iron–sulfur cluster (Ignarro, 1991; Bredt and Snyder, 1994). The physiological significance of S-nitrosothiol adduction is now widely accepted. S-Nitroso-

thiols at critical active site thiol residues are reported to regulate the function of several proteins (Stamler, 1994):

Under more extreme conditions, like severe oxidative and nitrosative stress, RNS react at other targets such as amino groups on DNA and tyrosine residues on proteins. RNS modification of target proteins results in modulation of their functional properties and can propagate downstream signals (Fig. 5).

RNS serve as an extraordinarily widespread effector of cellular functions. Generally, RNS-responsive targets serve sensory and regulatory roles in signal transduction. The target recognizes RNS and transduces the chemical signal into a functional response. Some of the signaling pathways involving RNS are discussed below.

In most cases the ultimate fate of NO is generally its oxidation to nitrate. Two enzymes, SNO lyase and flavo-hemoglobin, have been identified in *Escherichia coli* and

were found to denitrosylate S-nitrosylated proteins and oxidize NO to nitrate, respectively (Hausladen *et al.*, 1998).

Advantages of Utilizing NO and Its Congeners as Chemical Messengers

Signaling by RNS can be considered to be economical since cells do not use vesicular machinery to release it. Moreover, it uses receptor systems that are already found in the general regulatory machinery of cells, and NO can pass through and between cells with ease, due to its gaseous nature. Since RNS have many physiological actions in different tissues, their unstable nature is beneficial by allowing for truly local actions at the site of synthesis.

Another advantage is that the targets of RNS (heme iron, iron-sulfur clusters, and thiol groups) are commonly found in either allosteric or catalytic sites of the proteins. Thus, in a conducive chemical environment and at appropriate concentrations, RNS can modulate protein activity and trigger

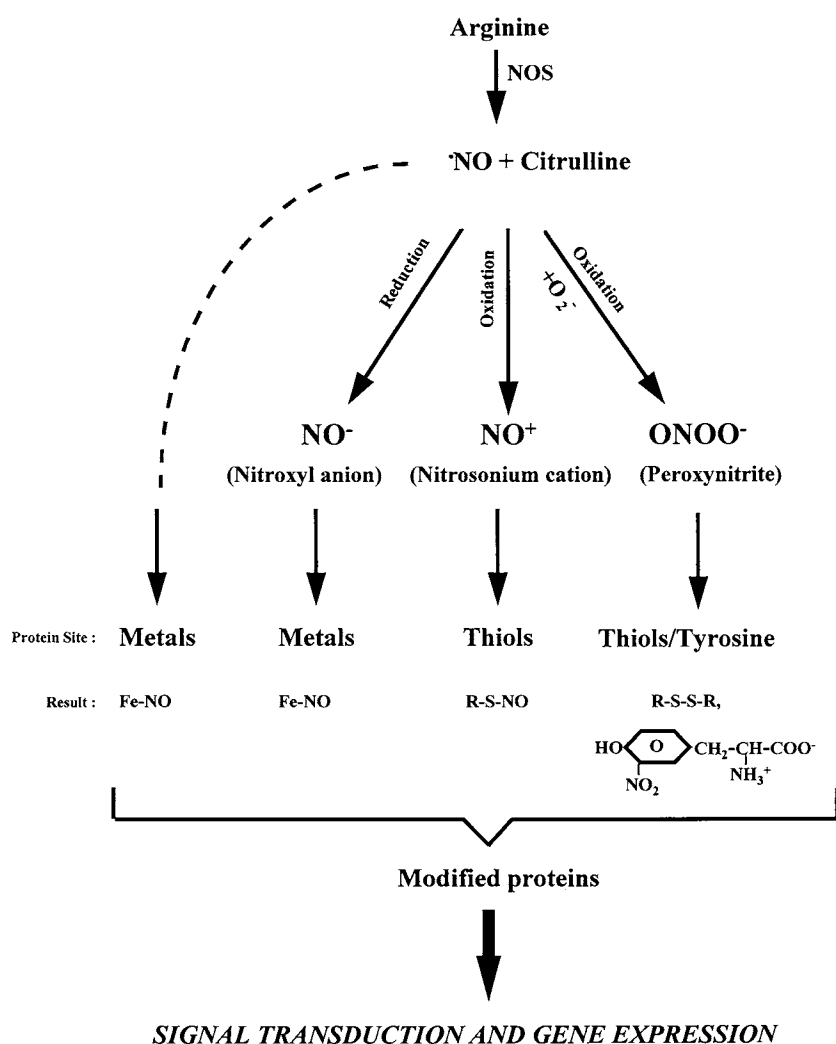

Figure 5 Initial molecular events of RNS signaling.

signaling. This mode of signaling is akin to phosphorylation of tyrosine, serine, and threonine residues.

What Is the Source of NO?

Endogenously, NO is derived enzymatically by the oxidation of one of the terminal guanidino nitrogen atoms of L-arginine by nitric oxide synthase (NOS), an enzyme which exists in three isoforms. nNOS (type I) (Bredt *et al.*, 1991) and eNOS (type III) (Lamas *et al.*, 1992), which were initially cloned from neuronal and endothelial cells, respectively, are Ca^{2+} -calmodulin dependent and expressed constitutively under most conditions. iNOS (type II), which was first identified in macrophages, is Ca^{2+} independent and inducible (Xie *et al.*, 1992). Most tissues have now been shown to express one or more of these isoforms.

The regulation of these enzymes is complex. The active enzyme requires five cofactors (FAD, FMN, heme, calmodulin, and tetrahydrobiopterin) and three cosubstrates (L-arginine, NADPH, and O_2) (Nathan and Xie, 1994). The enzymes are tightly controlled by substrate or cofactor availability, and by targeting of eNOS to plasmalemmal caveolae (small invaginations in the plasma membrane made up of caveolin protein), thus forming inactive complexes of eNOS and caveolin. This sequestration serves to prevent NO synthesis until the extracellular stimulus activates the complex. Moreover, because caveolae sequester many signaling molecules, including G proteins, receptors, and protein kinases, this microlocalization may aid in bringing NO and its target in close proximity.

Redox-regulated signaling involves multiple signaling cascades and concomitant regulation of several biological processes. We now highlight the cellular targets of NO, the major signaling pathways utilized, and examine their physiological relevance.

What Happens after RNS Modify Cellular Targets?

Interaction with Heme Iron

Metalloproteins contain redox-sensitive heme groups located at catalytic or allosteric sites. These are natural sensors of redox reactive species such as RNS because iron present in the heme group is a potent oxidizing agent. A variety of heme-containing proteins exhibit RNS-responsive control.

GUANYLYL CYCLASE

Guanosine 3',5'-monophosphate (cGMP) is utilized as an intracellular amplifier and second messenger by a wide spectrum of ligands to elicit diverse physiological responses. cGMP synthesis is catalyzed by multiple types of soluble and particulate guanylyl cyclase.

Soluble guanylyl cyclase is a family of heterodimeric heme proteins exhibiting a pyridine hemochrome visual absorption spectrum typical for ferriprotoporphyrin IX, and it

contains copper and iron as transition metals. The activation of soluble guanylyl cyclase by RNS is the principal mechanism of action in various RNS-induced cellular events, such as smooth muscle relaxation (Ignarro and Kadowitz, 1985; Ignarro, 1991) and inhibition of platelet adhesion (Radomski *et al.*, 1987). The cellular consequences of RNS-induced guanylyl cyclase activation are listed in Table I. RNS bind to the heme moiety of guanylyl cyclase and, by disrupting the plane of the heme iron, induce a conformational change that allosterically activates the enzyme. The cGMP synthesized further modulates an array of mediators including ion channels, phosphodiesterases, and protein kinases. Activation of guanylyl cyclase was the first RNS-induced signaling mechanism reported. To date, it remains the most important physiological pathway by which RNS propagate cellular signals.

NITRIC OXIDE SYNTHASE

NOS is a homodimer with a molecular mass of approximately 300 kDa. Its regulation is complex, with checkpoints at transcriptional, posttranscriptional, and posttranslational levels. Interestingly, RNS can inhibit the enzyme activity of NOS itself by posttranslational modification. Unlike guanylyl cyclase, this enzyme utilizes the heme prosthetic group in catalysis. The binding of RNS to either Fe(II) or Fe(III) heme may interfere with the conversion of ferric to ferrous iron required for catalysis and result in attenuation of enzyme activity. Thus, negative feedback inhibition is achieved (Griscavage *et al.*, 1994). This is likely to be a critical event in turning off NO synthesis and to be crucial for maintaining redox homeostasis.

Interaction with Iron–Sulfur Proteins

Iron–sulfur proteins are polymetallic structures whose iron atoms are linked to inorganic sulfides and are usually liganded to proteins by cysteine thiolates. These proteins are sensitive to oxidoreduction and have long been known as targets of O_2^- and H_2O_2 . In *in vitro* models, RNS were shown to yield complexes with [Fe–S] clusters. It is thought that peroxynitrite may react with iron–sulfur clusters, and, in contrast to a reversible reaction of RNS with heme, its reaction with iron–sulfur clusters results in the dissolution of the cluster.

ACONITASE

In addition to its participation in the citric acid cycle, the mammalian [4Fe–4S] cytoplasmic aconitase is also a regulator of iron homeostasis. RNS inhibit aconitase activity by disrupting [Fe–S] clusters. This disruption exposes its RNA binding site, permitting binding of the protein, now called the iron regulatory binding protein, to the iron-responsive element on transferrin receptor and ferritin mRNA. When bound to the iron-responsive element at the 3' end of transferrin receptor mRNA, it stabilizes the mRNA. However, when bound to the iron-responsive element at the 5' end of ferritin mRNA, it inhibits translation. Thus, RNS signal

Table I Cellular Events Regulated by the RNS/cGMP Signaling Pathway

Cell type	Cellular event
Smooth muscle	Vasodilation
Platelets	Antiaggregation
Sheep mitral cells	Olfactory memory formation by potentiation of glutamate release
Human neutrophils	Attenuates platelet-activating factor-induced release of elastase
Human myocardium	Negative inotropic effect
Human hepatocellular carcinoma cells	Hypoxic regulation of erythropoietin production
Human $\gamma\delta$ T lymphocytes	CD95-induced apoptosis
Bovine chondrocytes	Disruption of focal adhesion signaling complex
Rat smooth muscle, myocytes, pinealocytes, alveolar epithelial	Inhibits spontaneous depolarization of L-type Ca^{2+} channels
Rat thyroid follicular, Rat-2 fibroblasts	Activation of transcription from AP-1 responsive promoters
Rat aorta	Inhibition of α_1 -adrenergic receptor-induced <i>c-fos</i> and <i>c-jun</i> mRNA
Mouse splenic B cells	Inhibition of apoptosis by increasing expression of bcl-2
Rat hippocampus	Downregulation of prodynorphin mRNA, upregulation of proenkephalin mRNA
Rat pheochromocytoma PC12	Activation of transcription factor AP-1
Mouse hypothalamic GT1	Repression of hypothalamic gonadotropin-releasing hormone gene expression

through proteins involved in iron metabolism and regulates iron homeostasis (Drapier *et al.*, 1993; Jaffrey *et al.*, 1994).

SoxR

In response to microbial attack, activated macrophages produce various free radical species, including superoxide anion, hydrogen peroxide, and NO. However, bacteria possess several protective mechanisms against macrophage-induced oxidative and nitrosative stress. SoxR is a bacterial transcriptional activator requiring an iron–sulfur center for its activity. It is a homodimeric protein, and each monomer possess a $[2\text{Fe}-2\text{S}]$ cluster. Oxidation or nitrosation reversibly activates the FeS centers of SoxR protein which triggers the *soxS* gene. The product of the *soxS* gene further activates transcription of approximately 12 regulon genes, which code for defense proteins such as manganese superoxide dismutase, the DNA repair enzyme endonuclease IV, and glucose-6-phosphate dehydrogenase. Activation of *soxRS* regulon genes confers resistance to attack by activated macrophages. Thus, redox-sensing FeS centers detect oxidative and nitrosative stress and help bacteria survive by triggering the co-

ordinated expression of defense genes (Hidalgo and Demple, 1994).

Interaction with Thiol

Cysteine residues are known to be important for maintaining the native conformation of proteins; they are critical residues at the active sites of enzymes and are the most reactive residues to RNS at physiological pH. Furthermore, cysteine residues are sites for covalent attachment of other regulatory molecules, for example, lipid and ADP-ribose. RNS react with thiols to form a variety of oxidized thiol species including sulfenic acids, disulfides, mixed disulfides, nitrosothiol, and covalent NAD–thiol linkages.

Under physiological aerobic conditions, oxidation of NO yields NO^+ -like species that have a high affinity for nucleophilic centers such as thiols, forming nitrosothiol (RSNO). Thiol nitrosation may also be mediated by the oxidative activation of NO through binding to transition metals. Nitrosothiol formation by metal ion-mediated formation of NO^+ is likely to be faster than via reactions of NO and O_2 . Also, peroxynitrite anion is capable of nitrosating thiols. Nitrosothiols have a longer half-life than free NO and are an important pool from which redox signals can be generated (Stamler *et al.*, 1992b; Stamler, 1994). The S-nitrosation of protein thiols is a form of posttranslational modification and may either activate or inactivate protein function.

PROTEINS ACTIVATED BY S-NITROSOTHIOL FORMATION

Ras The monomeric G protein Ras is a key element of many signaling pathways. It is implicated in the regulation of proliferation and differentiation by tyrosine kinase and G-protein-coupled receptors. Activation of Ras involves guanine nucleotide exchange factor-mediated exchange of GDP for GTP and subsequent interaction with effector proteins. Effector proteins transduce signals via several pathways and induce cellular responses.

RNS were found to activate Ras in human T cells, rat pheochromocytoma cells, and human endothelial cells. Nitrosothiol formation at a single cysteine residue, Cys¹¹⁸ of Ras, was found to trigger GDP/GTP exchange (Lander *et al.*, 1996). Thus, RNS activate Ras by a mechanism akin to that of growth factors. However, it differs in that it bypasses the requirement for guanine nucleotide exchange factors by directly modifying Ras and triggering GDP/GTP exchange (Fig. 6).

Mitogen-activated protein kinases are important components of the Ras-dependent signal transduction pathway. S-Nitrosated Ras was found to trigger activation of three mitogen-activated protein kinases, extracellular signal-regulated kinase, c-Jun NH_2 -terminal kinase, and p38 MAP kinase. Interestingly, c-Jun NH_2 -terminal kinase and p38 MAP kinase are also activated by proinflammatory cytokines and environmental stress. Further downstream, RNS were found to activate the transcription factor NF- κ B. This activation was observed in human peripheral blood mono-

GEF: Guanine nucleotide exchange factor.

Figure 6 RNS modification of Ras bypasses the classic requirement for guanine nucleotide exchange factor (GEF).

nuclear cells, T cells, and pheochromocytoma cells, and it depended on S-nitrosothiol formation at Cys¹¹⁸ residue of Ras. Identifying the signals immediate to RNS-induced Ras activation (which includes Ras effectors such as phosphoinositide 3-kinase, Raf-1, and protein kinase C- ζ) and downstream intermediate signals leading to NF- κ B activation will help in deciphering the RNS-induced Ras pathway. Because Ras is also activated by other redox modulators such as hemin, mercuric chloride, and hydrogen peroxide, it may serve as a general sensor of cellular redox stress and enable the cell to respond appropriately to the external milieu.

Calcium Release Channel (Ryanodine Receptor) Ryanodine receptors belong to a multigene family of channel proteins. They are localized at the junctional sarcoplasmic reticulum in muscle and the endoplasmic reticulum in epithelial and neuronal cells. These receptors are sensitive to the muscle paralyzing alkaloid, ryanodine, and are responsible for release of Ca²⁺ from intracellular stores, which activates contraction. Ion channels are reported to be redox regulated via their sulfhydryl groups. RNS were found to induce ryanodine receptor channel opening and Ca²⁺ release from skeletal and cardiac sarcoplasmic reticulum into the cytoplasm. Polynitrosation of up to 12 free thiols of the cardiac

calcium release channel reversibly activates the channel, which then releases Ca^{2+} from the sarcoplasmic reticulum in response to a muscle action potential. Interestingly, in contrast to S-nitrosation, the oxidation of thiol groups has no effect on channel function, suggesting a specificity of nitrosothiol-induced activation (Xu *et al.*, 1998). Thus, direct interaction of RNS with thiols of the cardiac calcium release channel regulates force in the contrasting muscle and thereby controls excitation–contraction coupling.

Tissue-Type Plasminogen Activator The normal endothelium secretes cardioprotective mediators such as RNS and tissue-type plasminogen activator (t-PA). t-PA is involved in the activation of the fibrinolytic system. S-Nitrosation of t-PA at Cys⁸³ endows the enzyme with vasodilatory and antiplatelet properties and enhances the catalytic efficiency of plasminogen activation in the presence of fibrin (Stamler *et al.*, 1992c). S-Nitrosated t-PA was also able to attenuate cardiac necrosis after myocardial ischemia–reperfusion and inhibited a neutrophil–endothelium interaction. This latter effect may involve a decrease in expression of the adhesion molecule, P-selectin. Hence, S-nitrosation of t-PA converts a simple protease into a pleiotropic antithrombotic agent.

Calcium-Dependent Potassium Channels The endothelium controls vascular smooth muscle tone by secreting relaxing and contracting factors. RNS, also called endothelium-derived relaxing factor, activate calcium-dependent potassium channels leading to hyperpolarization of the vascular smooth muscle cell leading to vasodilation. The mechanism of activation involves S-nitrosation of thiols and eventual disulfide formation of vicinal thiols accompanied by the release of NO^- (Bolotina *et al.*, 1994). Hence, RNS regulate vascular tone by activation of calcium-dependent potassium channels, in addition to activation of guanylyl cyclase as discussed above.

PROTEINS INACTIVATED BY NITROSOTHIOL FORMATION

N-Methyl-D-Aspartic Acid Receptor In the central nervous system, glutamate is the main excitatory neurotransmitter. Activation of the N-methyl-D-aspartic acid (NMDA) subtype of excitatory amino acid receptors by glutamate results in increased activity of nNOS in the brain. The NO produced acts as a neurotransmitter and is implicated in a variety of functions including synaptic plasticity, cerebral circulation, regulation of circadian rhythm, and production of cerebrospinal fluid. The endogenous NO was found to activate Ras–MAP kinase pathway. However, excessive NMDA receptor activation leads to overproduction of NO, resulting in neuronal damage due to cell death. Paradoxically, the NMDA receptor is inhibited by RNS at a redox modulatory site. Inactivation of NMDA receptor is thought to be due to S-nitrosation at thiol residues and eventual disulfide bond formation (Lipton *et al.*, 1993). RNS provide a neuroprotective signal by inhibiting the NMDA-receptor and hence preventing neural injury caused by high levels of glutamate and RNS (Fig. 7).

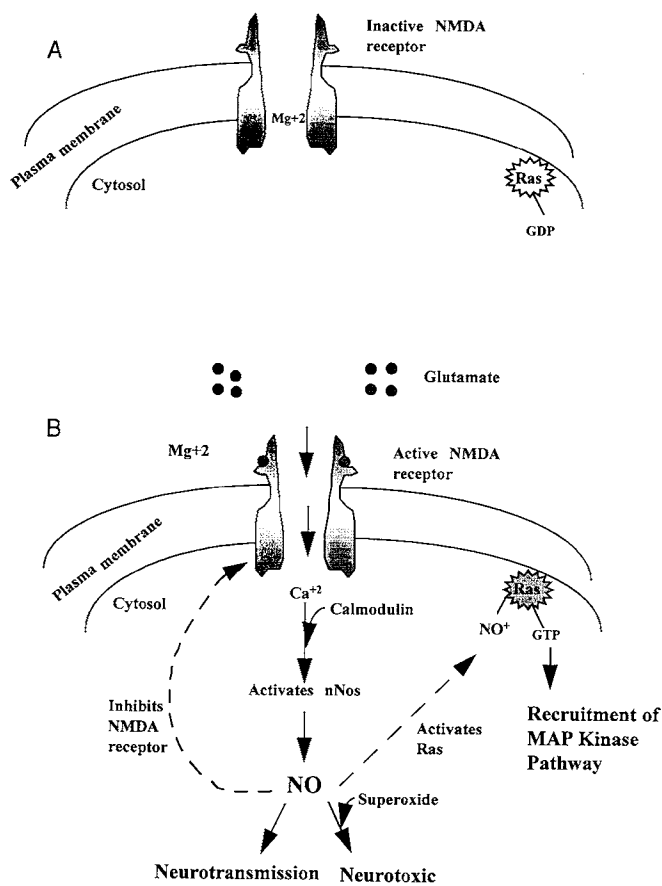

Figure 7 Diverse role of RNS in neurons.

Transcription Factors Transcription factors transduce signals to the transcriptional apparatus by binding to specific DNA sequences of the genes they regulate. Studies suggest that mammalian and bacterial transcription factors can be regulated by S-nitrosation.

NF- κ B The classic, inactive cytoplasmic form of NF- κ B exists in a trimer of three subunits, p65, p50, and I κ B α . On activation, the inhibitory subunit I κ B α dissociates, and the dimer of p50/p65 translocates to the nucleus. In addition to NF- κ B binding sites in the immunoglobulin κ chain gene, the site has been identified in many other genes including those for cytokines, cytokine receptors, cell adhesion molecules, HIV provirus, and, interestingly, iNOS.

RNS were shown to activate NF- κ B in human peripheral blood mononuclear cells. NF- κ B activation in human T cells and rat pheochromocytoma cells was found to be dependent on RNS-induced S-nitrosation of Ras at the Cys¹¹⁸ residue and subsequent Ras activation (Lander *et al.*, 1995a,b). These studies demonstrate that RNS can trigger an NF- κ B response and may provide a mechanistic basis by which RNS trigger NF- κ B-dependent gene expression.

In contrast, in nonlymphoid astroglial cells, it was observed that RNS derived from a spermine NONOate inhibits formation of an NF- κ B–DNA complex. The direct interac-

tion of RNS with recombinant p50 and p65 subunits was studied, and RNS donors were found to inactivate the DNA-binding activity of the recombinant subunits. The p50 subunit was S-nitrosated at Cys⁶², and this modification seemed to be responsible for inhibition in DNA binding. The Cys⁶² residue of the p50 subunit is conserved in the NF- κ B transcription factor family. Moreover, it is located in the peptide loop that makes specific contacts with the DNA consensus sequence. This residue is redox sensitive, as its oxidation and subsequent intersubunit disulfide linkage also abrogates its DNA binding activity (Matthews *et al.*, 1996). Since the promoter of the iNOS gene contains an NF- κ B binding motif, RNS inhibit iNOS gene expression by inhibiting NF- κ B activation and thus regulate the enzyme by feedback inhibition.

Hence, like oxidative stress, in some settings nitrosative stress activates NF- κ B and may evoke an inflammatory response. In other settings, RNS can downregulate its own synthesis, likely through direct modification of the NF- κ B subunits. This dual functionality of RNS highlights the complex signaling behavior of free radicals.

OxyR In a cell, intramolecular disulfide bond formation often results in inactivation of protein activity. However, bacteria utilize this mechanism to activate the transcription factor OxyR, which like SoxR, rescues bacteria from oxidative and nitrosative stress. It induces expression of protective genes such as hydrogen peroxidase I and glutathione reductase. The conserved residues, Cys¹⁹⁹ and Cys²⁰⁸, are critical for its activation by oxidative stress. Activation is mediated by intramolecular disulfide bond-induced conformational changes between these two cysteine residues. Nitrosative stress is also known to activate OxyR by reacting with cysteine residues (Zheng *et al.*, 1998). It is worthwhile to note that bacterial transcription factors have evolved sophisticated mechanisms to respond to and survive stressful redox environments.

Interaction with Heme and Thiol

HEMOGLOBIN

When administered systemically, cell-free hemoglobin leads to hypertension. This effect is thought to be due to scavenging of RNS by hemoglobin via its heme iron. Hence, many experimental studies utilize hemoglobin to determine RNS-specific effects. Nevertheless, direct interaction of hemoglobin with RNS was not found to modulate any functional properties of hemoglobin. More recently it was demonstrated that hemoglobin can be S-nitrosated. This discovery highlights the importance of RNS in the respiratory cycle and the dynamic properties of hemoglobin in vasoregulation. In the microcirculation and venous system, RNS reside predominantly on the T-state (deoxy) α -chain heme iron of hemoglobin. The β -chain of hemoglobin possesses a highly reactive thiol group at cysteine-93, which is conserved among mammalian species. When venous blood enters the lungs, oxygen favors an allosteric transition with

RNS group exchange from the α -chain heme to the β -chain (Cys⁹³) thiol, and O₂ attaches to the heme. This R state (oxy) structure of hemoglobin then re-enters the circulation and, when faced with an O₂ gradient in resistance vessels, releases both O₂ and RNS. The RNS released may bind to the abundant glutathione present in erythrocytes, and the S-nitroso-glutathione formed can then dilate the blood vessels. This augments O₂ delivery to the peripheral tissues (Gow and Stamler, 1998). This highlights how redox-regulated residues are conserved at a strategic site and how the allosteric changes in protein conformation control dynamic functions of the protein.

Cytotoxic Consequences

At high concentrations, RNS are cytotoxic. This action of RNS is utilized as a defense mechanism against pathogens and tumor cells. Some of the cytotoxic signals include the following.

RNS inactivate several mitochondrial iron-sulfur enzymes involved in ATP synthesis. These include NADH:ubiquinone oxidoreductase, NADH:succinate oxidoreductase, and *cis*-acotinase. Inactivation of GAPDH by S-nitrosation inhibits glycolysis. RNS bind the nonheme iron of ribonucleotide reductase, attenuating its activity and inhibiting DNA synthesis. Quenching of tyrosyl radical by RNS may be another mechanism involved in inactivation of this important enzyme. Iron of the iron-storage protein ferritin is also a target of RNS. This interaction leads to the release of free iron, which may cause lipid peroxidation. Like other free radicals, RNS can damage DNA by base deamination, resulting in neurotoxicity (Nathan, 1992). Many of the above cytotoxic events occur at high concentration of RNS and are the causative pathways for cell damage seen in ischemia-reperfusion injury, inflammation, and graft rejection.

The identification of endogenous NO was a hallmark discovery (Furchgott and Zawadzki, 1980; Ignarro *et al.*, 1987). It provided a mechanistic understanding of many physiological processes. Extensive studies in the field of RNS-induced signaling have helped us to appreciate the sophistication as well as simplicity of this protean molecule. In response to environmental cues, RNS can posttranscriptionally modify proteins. This leads to allosteric or catalytic modulation and appropriate signaling. Extensive studies discussed above suggest that S-nitrosation of cysteine is as crucial as phosphorylation of tyrosine, serine, and threonine in signal transduction.

A Shift in Paradigm: Reactive Oxygen Species— From Cytotoxic Agents to Signal Transducers?

Reactive oxygen species (ROS) are commonly associated with a scenario of indiscriminate cellular damage. However, new studies demonstrate that ROS are essential components of redox signaling. At subtoxic concentrations, oxidants

such as superoxide ($O_2^{\cdot-}$), hydroxyl radicals (HO^{\cdot}), and lipid hydroperoxides serve as signaling molecules. Some of the physiological events regulated by ROS include cell growth, cell adhesion, apoptosis, ion transport, neuromodulation, and transcription. Many growth factors, hormones, and cytokines are thought to generate ROS on interacting with their respective receptors. Antioxidants were found to inhibit the signaling induced by platelet-derived growth factor, insulin, angiotensin II, vitamin D₃, parathyroid hormone, transforming growth factor- β 1, interleukin 1 β , and tumor necrosis factor α . The use of antioxidants has established the role of redox species in the propagation of ligand-stimulated cell signaling (Sundaresan *et al.*, 1995).

How Do ROS Signal?

As discussed previously, two important components of signal transduction are Ca^{2+} signaling and protein phosphorylation. Oxidants were found to utilize these components of the cell machinery to relay signals. Some of the signaling events regulated by ROS include activation of transcription factors AP-1 and NF- κ B. ROS were also found to activate the enzyme phospholipase A2, products of which play critical roles in the immune response and inflammation.

Oxidants such as H_2O_2 , *tert*-butyl hydroperoxide, and linoleic acid hypoperoxide were found to increase cytosolic Ca^{2+} levels and stimulate Ca^{2+} signaling. Ca^{2+} was found to be effluxed mainly from the sarcoplasmic Ca^{2+} -release channels in muscle cells and inositol phosphate-regulated Ca^{2+} channels on endoplasmic reticulum in endothelial cells. Superoxide induced protooncogene expression in proximal tubular epithelium by mobilizing extracellular Ca^{2+} instead of intracellular stores. Oxidants are even known to recruit Ca^{2+} -binding proteins and the mitochondrial Ca^{2+} store for signaling.

Oxidants also relay signals by modulating protein phosphorylation. They have been reported to activate tyrosine and serine/threonine phosphorylation. Although the mechanism is not yet clear, it may involve direct activation of kinase activity or inhibition of phosphatases. Some of the phosphorylation events modulated by oxidants include activation of insulin receptor tyrosine kinase activity, p56lck, ZAP-70, p72syk, protein kinase C, and MAP kinase. As discussed in preceding sections, cysteine is a sensor of redox changes. Tyrosine phosphatases and protein phosphatases 1 and 2 have reactive cysteine residues in their active site and hence are highly susceptible to inactivation by oxidant-mediated modification of cysteine residues. However, modification of cysteine in the regulatory domain of protein kinase C triggers its activity (Staal *et al.*, 1994; Suzuki *et al.*, 1997). Redox-induced modification of the CYS¹¹⁸ residue of Ras protein is known to activate GDP/GTP exchange on this G protein. Redox modification of cysteine and Fe-S clusters also activates the bacterial transcription factor, OxyR and SoxR, respectively (Lander, 1997). A thiol group of ubiquitin-conjugating enzyme is also reported to be suscep-

Table II Some of the Direct Cellular Targets Utilized by RNS and ROS for Signaling

RNS	ROS
Guanylyl cyclase	Phospholipase A2
Nitric oxide synthase	Insulin receptor
Aconitase	Ras
Ras	Tyrosine phosphatase
Calcium-release channels	Protein phosphatase 1 and 2
Calcium-dependent potassium channels	Protein kinase C
Tissue-type plasminogen activator	Ubiquitin-conjugating enzyme
N-Methyl-D-aspartic acid receptor	SoxR
Hemoglobin	NF- κ B
SoxR	OxyR
NF- κ B	AP-1
Oxy R	

tible to redox changes, with S-thiolation inhibiting the enzyme activity (Obin *et al.*, 1998).

Cellular homeostasis is a tightly controlled phenomenon with checkpoints and regulation at different levels. The ultimate outcome of signaling induced by RNS and ROS will depend on various cellular factors. The concentration of reactive species is a very important determinant in signaling. This could be regulated at the level of generation or by the free radical scavengers of the cell. Second, the physicochemical nature of the cellular redox state and targets will also influence signaling. The cellular targets utilized by RNS and ROS for signaling are listed in Table II, and some of the factors that favor RNS and ROS as signaling molecules are summarized in Table III.

In conclusion, RNS and ROS have been identified as second messengers that control crucial physiological events. Although the concept of reactive free radicals as signaling molecules is new and requires one to visualize in a chemical manner, rather than in the traditional steric manner, RNS and ROS should be considered as part of the signal transduction cascade. However, a thin line exists between its role as a cytotoxic or signaling molecule. Studies in redox signaling have highlighted how cells effectively utilize redox chemistry to mediate specific signaling that dictates crucial biolog-

ical events. Many events in every organ of the body are regulated directly or indirectly by RNS and ROS, and many more significant pathways and cellular outcomes are yet to be deciphered. Hence, in-depth studies in the field of RNS- and ROS-induced signaling and gene expression will provide insights into various physiological processes. Ultimately, elucidating the role of RNS and ROS in cell signaling will yield novel targets for drug development.

AN ANTIOXIDANT IS ANY SMALL MOLECULE OR PROTEIN THAT INHIBITS OXIDATION REACTIONS, IRRESPECTIVE OF THE MECHANISM. INHERENT CELLULAR PROPERTIES OR CHANGES IN DIFFERENTIATED CELL FUNCTION THAT LEAD TO INHIBITION OF MOLECULAR OXIDATION REACTIONS CAN ALSO BE PERCEIVED AS ANTIOXIDANT IN NATURE. THIS IS A NECESSARILY BROAD VIEW, BECAUSE THE OXIDANTS FORMED BY BIOLOGICAL SYSTEMS COME IN A BROAD ARRAY OF SHAPES AND SIZES, WITH CORRESPONDING VARIATIONS IN STABILITY, CHEMICAL REACTIVITY, AND SPECIFICITY. SIMILARLY, THE REGULATORY MECHANISMS THAT CONTROL CELLULAR OXIDANT PRODUCTION, INJURIOUS RESPONSES, AND DEFENSE REACTIONS REQUIRE A BROAD VIEW OF ANTIOXIDANT REACTIONS. WHILE EMBRACING THIS EXPANSIVE DEFINITION OF AN ANTIOXIDANT, WE ARE NOW FACED WITH THE CHALLENGE OF UNDERSTANDING THE PROFOUND INFLUENCES THAT NO EXERTS IN REGULATING BOTH PRO-OXIDANT AND ANTIOXIDANT REACTIONS AT THE CELL AND MOLECULAR LEVEL. THIS CHEMICALLY SIMPLE MOLECULE ENLISTS MULTIPLE MOLECULAR MECHANISMS WHEN MEDIATING ANTIOXIDANT ACTIONS AND ACTS AT MULTIPLE LEVELS IN TISSUES, OFTEN SIMULTANEOUSLY. THESE MECHANISMS INCLUDE DIRECT CHEMICAL TERMINATION OF FREE RADICAL REACTIONS, COMPLEXATION WITH REACTIVE METAL CENTERS, REGULATION OF GENE EXPRESSION OF KEY OXIDANT SCAVENGERS, AND ALTERATION OF INFLAMMATORY CELL-TARGET CELL INTERACTIONS. FOLLOWING, WE ADDRESS THE CONCEPT OF “INACTIVATING” NO BY REACTION WITH SUPEROXIDE ($O_2^{\cdot-}$) AND PRESENT THE PRINCIPAL MECHANISMS WHEREBY NO CAN MANIFEST OXIDANT-PROTECTIVE PROPERTIES. IT IS IMPORTANT TO NOTE THAT THE FOCUS OF THIS CHAPTER IS TO DEFINE MECHANISMS UNDERLYING DIRECT PRO-OXIDANT AND ANTIOXIDANT ACTIONS OF NO. ALTHOUGH OTHER PROPERTIES OF NO, ALONG WITH CELLULAR LOCALIZATION AND MODULATION OF NITRIC OXIDE SYNTHASES, ALSO PLAY AN IMPORTANT ROLE IN CONTROLLING NO FUNCTION, THESE ARE NOT DISCUSSED IN DETAIL AS THEY ARE COVERED IN DEPTH ELSEWHERE IN THIS VOLUME.

Radical Termination Reaction between Nitric Oxide and Superoxide—Not an Antioxidant Property of Nitric Oxide

After the description of endothelium-derived relaxing factor (EDRF) as nitric oxide (NO), there was early confusion as to whether the reaction of NO with superoxide ($O_2^{\cdot-}$)

was pro-oxidative or antioxidant in nature, since the interaction of $O_2^{\cdot-}$ with NO often induced subsequent abrogation of NO-dependent physiological responses (Rubanyi *et al.*, 1991). Although this was termed an inactivation or scavenging reaction, confusion arose from the failure to appreciate at the time that the “inactivation” product of the diffusion-limited reaction of NO with $O_2^{\cdot-}$ was actually a potent oxidizing and nitrating species, peroxynitrite ($ONOO^-$)

(Beckman *et al.*, 1990; Hogg *et al.*, 1992; Ischiropoulos, 1998). We now know that when ONOO^- is formed in the predominant detection system for O_2^- , the reduction of ferrous cytochrome *c* ($\text{Cyt } c^{2+}$), the ONOO^- will reoxidize ferric cytochrome *c* ($\text{Cyt } c^{3+}$), in addition to mediating other heme and amino acid modifications of this protein [Eqs. (1) and (2)] (Thomson *et al.*, 1995; Cassina *et al.*, 2000).

Thus, when investigators were measuring the influence of endogenously produced or exogenously administered NO on cell O_2^- production, a secondary oxidant was being produced that also impairs O_2^- detection. Knowledge of the oxidative chemistry and cell biology of the reaction of NO with O_2^- has advanced significantly since then and can be broadly summarized by Fig. 1. The reaction of NO with O_2^- to yield ONOO^- generates both oxidized and nitrated products on reacting with a diverse array of biomolecules. Both the oxidation and nitration products of ONOO^- will manifest secondary biological effects; thus, the view that O_2^- inactivates NO is a simplification that does not take into account the diverse biological effects of this reactive nitrogen species.

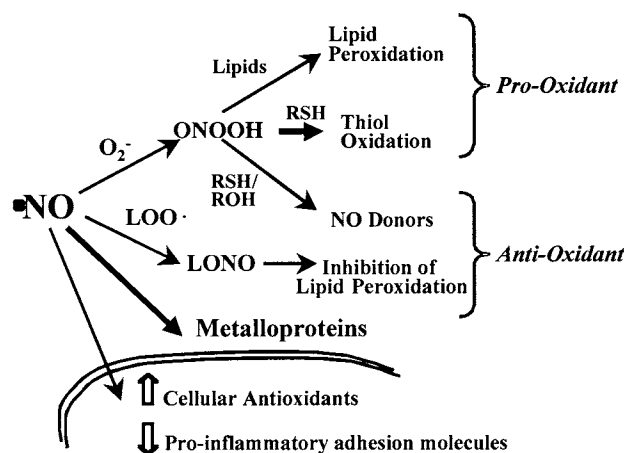

Figure 1 Pro- and antioxidant actions of NO. Nitric oxide can exert both pro-oxidant and antioxidant effects, depending on other reactants and on the nature of the reaction. Pro-oxidant effects associated with NO are generally attributed to formation of ONOO^- and subsequent oxidation of lipids or thiols. For example, lipid peroxidation of low density lipoprotein (LDL) is a key step in the oxidative hypothesis of atherosclerosis, and oxidation of cellular thiols, namely, glutathione, depletes antioxidant levels and thus decreases the capacity of cells to survive an oxidative insult. On the other hand, ONOO^- can exhibit antiatherosclerotic effects via reaction with thiols and hydroxide functional groups on carbohydrates, yielding NO donor compounds. Release of NO from these compounds can then protect the vasculature through a number of mechanisms, including direct reaction with $\text{LOO}\cdot$, which results in a termination of lipid peroxidation. Furthermore, long-term exposure of vascular cells to NO can increase cellular antioxidants and downregulate expression of adhesion molecules during inflammation. Important metalloproteins modulated by NO activity include lipooxygenases and cyclooxygenases. Peroxynitrite also reacts with carbon dioxide in a reaction that promotes tyrosine nitration.

In broad perspective, it is generally viewed that the reaction of NO with O_2^- will lead to pro-oxidative effects, but there are always exceptions in complex biological milieus. For example, NO might divert O_2^- reactivity away from a particularly toxic target molecule or endpoint reaction, and vice versa. At low concentrations, ONOO^- may act as a signaling molecule, explaining cytoprotective effects that have been reported in both platelets and vascular systems (Go *et al.*, 1999; Moro *et al.*, 1994; Brown *et al.*, 1998). In a cellular milieu this could be occurring through the competitive and kinetically favorable “redirection” of the reactivities of both NO and O_2^- to the formation of the highly thiol-reactive product ONOO^- . The net outcome can then be the rerouting of the individual free radical reactivities of NO and O_2^- via ONOO^- formation and its subsequent reaction with the regenerable antioxidant glutathione (GSH) and modification of thiol-containing proteins in signaling cascades.

Regulation of Nonenzymatic and Enzymatic Lipid Peroxidation

General Aspects of Lipid Oxidation

One of the first indications that NO could inhibit lipid peroxidation came from studies of the heme protein- and metal-initiated lipid peroxidation reactions underlying food rancidification (Kanner, 1979). Indeed, it had long been known that oxidation of meat could be prevented by the addition of nitrite (NO_2^-), resulting in the formation of a nitroso complex with the heme iron of myoglobin. More recently, concepts related to this and other mechanisms of regulation of lipid oxidation by NO have been extended to understanding the pathophysiology of human diseases. Most notably, in atherosclerosis it has been argued that lipid peroxidation plays a central pathogenic role. We now have more insight into the protective roles that NO can play toward oxidizing membrane and lipoprotein lipids (Rubbo *et al.*, 1994; Hogg and Kalyanaraman, 1999; O'Donnell *et al.*, 1997), and we present as background some of the basic elements of lipid peroxidation biochemistry.

Nitric oxide is an ideal molecule to mediate lipid oxidative reactions. First, as a pro-oxidant, it reacts with O_2^- to yield the initiator of lipid oxidation, ONOO^- . In contrast, from an antioxidant perspective, the physical properties of NO result in a highly lipid-protective role in the absence of O_2^- levels that would support significant ONOO^- production. The unpaired electron of NO makes it possible for NO to readily react with other radical intermediates formed during lipid oxidation and thus terminate radical reaction sequences. The charge neutrality of NO, its lipophilicity, and its low Stokes radius also permits facile diffusion through as well as concentration in membranes and lipoproteins (Liu *et al.*, 1998). Finally, the direct or indirect reactivity of NO with heme-, iron-sulfur-, and thiol-containing proteins will modulate downstream reactions that can either stimulate or inhibit lipid oxidation.

Controlled lipid peroxidation reactions are essential in normal physiology. For example, the directed and stereo-specific insertion of oxygen into unsaturated fatty acids is used by lipoxygenases and cyclooxygenases to generate a family of lipid oxidation products that serve as signaling molecules. Nonenzymatic lipid oxidation mechanisms lack this specificity and, in the absence of sacrificial antioxidants, have the capacity for uncontrolled amplification reactions of increasing intensity, known as propagation reactions.

The different facets of lipid peroxidation reactions start with the initiation event, in which a hydrogen atom is abstracted from an unsaturated fatty acid, yielding $L\cdot$ (Fig. 2). In some cases not only radical species, but also metal complexes and metalloproteins can serve to abstract hydrogen atoms from unsaturated fatty acids (as in the case of lipoxygenases and cyclooxygenase). Then, molecular oxygen rapidly adds to yield an alkyl peroxy radical ($LOO\cdot$). The next phase involves propagation reactions, catalyzed by the reaction of peroxy radical intermediates with vicinal unsaturated fatty acids. At this stage, the lipid peroxidation process is susceptible to termination by lipophilic antioxidants (e.g., tocopherols, carotenoids, lycopenes), via reduction of the peroxy radical to a hydroperoxide ($LOOH$). Reduced metals enter into the reaction scheme by reacting with $LOOH$ species and forming the alkoxyl radical ($LO\cdot$) and epoxyallylic radical species $[L(O)\cdot]$, both of which are capable of stimulating lipid oxidation by catalyzing further propagation reactions. Importantly, NO can act at two key steps in this reaction pathway to inhibit lipid peroxidation. One is the kinetically preferred termination of lipid peroxy radicals via NO reaction with $LOO\cdot$ intermediates, and the other is by reaction with catalytic metal centers that can then either initiate or propagate lipid peroxidation. As will be described, NO can (a) inhibit controlled enzymatic reactions that generate oxidized lipid signaling molecules and (b) limit membrane and lipoprotein oxidation reactions. Diverse mechanisms will initiate lipid peroxidation when tissues are exposed to inflammatory mediators or redox-active xenobiotics. Before addressing these mechanisms, it is important to convey that secondary products of NO are also capable of initiating lipid oxidation.

Initiation of Lipid Peroxidation by NO-Derived Species

A number of NO-derived reactive species can initiate lipid peroxidation, including nitrogen dioxide ($NO_2\cdot$) and, most notably, $ONOO^-$, which displays unique properties as a mediator of lipid oxidation. On a molar basis, $ONOO^-$ is a more potent lipid oxidant than hydrogen peroxide (H_2O_2), and, unlike H_2O_2 , it does not require metal catalysis (Radi *et al.*, 1991). Lipid oxidation mechanisms frequently depend on metal-mediated decomposition of a preexisting lipid peroxide, whereas $ONOO^-$ can attack lipids in microenvironments where metals are not present or are bound in catalytically inactive forms. Typically, initiation of lipid oxidation by free radical or oxidizing species in key tar-

Figure 2 Lipid peroxidation and targets for NO interaction. In this scheme, lipid oxidation is initiated in an unsaturated fatty acid (LH) to form the alkyl radical ($L\cdot$). The alkyl radical in turn reacts rapidly with oxygen, thus precluding effective scavenging of this species, and forms the peroxy radical ($LOO\cdot$). Peroxy radicals react slowly with vicinal lipids in the propagation phase of peroxidation (dotted lines) and can thus be effectively scavenged.

gets such as low density lipoprotein (LDL) requires depletion of endogenous antioxidants to a critically low level before significant unsaturated fatty acid oxidation occurs; however, this precept is now not felt to be applicable to atherosclerotic lesions (Niu *et al.*, 1999). Importantly, because of its reactivity, $ONOO^-$ can bypass lipophilic antioxidant defenses to directly oxidize unsaturated fatty acids (Darley-Usmar *et al.*, 1992). Thus, once formed, $ONOO^-$ is capable of promoting a number of reactions that are potentially atherogenic, including the oxidation of LDL (Hogg *et al.*, 1992).

Finally, the inflammatory conditions during which NO and $ONOO^-$ are generated can have relatively greater or lower concentrations of $O_2^{\cdot-}$. This leads to the interesting manifestation of either pro-oxidant or antioxidant actions of NO (Figs. 1 and 3) (Rubbo *et al.*, 1994). When NO does not exceed local $O_2^{\cdot-}$ concentrations, NO will stimulate lipid oxidation via $ONOO^-$ formation and reaction. When NO is replete in a microenvironment and in “excess” of $O_2^{\cdot-}$, it can manifest a predominantly inhibitory role toward lipid peroxidation via termination of $LOO\cdot$. Increases in rates of tissue NO production may thus restore the balance between NO and $O_2^{\cdot-}$ in favor of NO and suppress both chemical and secondary cellular components of atherosclerosis or other tissue inflammatory processes (Darley-Usmar *et al.*, 1992). This lipid-protective action of NO is even more likely to occur when non-superoxide-dependent mechanisms are initiating lipid oxidation (e.g., reduced transition metals, peroxy radicals), because $ONOO^-$ formation would not be expected. In support of these concepts, it is noted that NO donor agents protect cells from damage elicited by transition metals, H_2O_2 , alkyl hydroperoxides, oxidized LDL, and xanthine oxidase-derived $O_2^{\cdot-}$ and H_2O_2 (Malo-Ranta *et al.*, 1994; Gutierrez *et al.*, 1996; Rubbo *et al.*, 1996; Jessup *et al.*, 1992; Hogg *et al.*, 1993; Yates *et al.*, 1992). The precu-

Figure 3 The influence of different rates of O₂⁻ and ·NO generation on liposome membrane lipid oxidation. Phosphatidylcholine (PC) liposomes (6.6 mg ml⁻¹) were oxidized for 30 min in stirred incubations containing 50 mM potassium phosphate, 100 μM EDTA-Fe³⁺, pH 7.4. Superoxide was generated by xanthine oxidase (XO) plus 10 mM acetaldehyde, and GSNO was used as a source of NO. XO and GSNO concentrations ranged up to 5 mU ml⁻¹ for XO and 660 μM for GSNO and were calibrated to give the noted proportional rates of O₂⁻ and ·NO production, with maximal rates of radical production being 1 μM min⁻¹ for each at a ratio of 1:1 for O₂⁻ and ·NO (adapted from Rubbo *et al.*, 1994).

sor of NO synthesis, L-arginine, may also work through a similar mechanism (Drexler *et al.*, 1991; Cooke *et al.*, 1992).

Radical Termination Reactions between Nitric Oxide and Peroxyl Radicals

It is evident from the previous sections that more than one mechanism for initiation of lipid oxidation may be important in atherosclerosis and other inflammatory diseases, lending support to the strategy of targeting protective interventions toward the second stage of the peroxidation process, LOO·-mediated propagation reactions, rather than by limiting initiation events. The importance of LOO· in membrane and lipoprotein oxidation lies in the fact that it allows lipid peroxidation to be self-sustained through regeneration and recruitment of more unsaturated fatty acid into the cycle (Fig. 2). In this milieu of autocatalytic propagation reactions, NO can intervene by avidly reacting with lipid epoxyallylic radical [L(O·)], alkoxyl radical (LO·), and LOO· species with rate constants of $\sim 2 \times 10^9 M^{-1} s^{-1}$, yielding both nitrogen oxide- and hydroperoxide-containing products (Wallington *et al.*, 1992; O'Donnell *et al.*, 1999a; Maricq and Szenté, 1996; Frost and Smith, 1990; Padmaja and Huie, 1993). The reaction of NO with LOO· species would thus readily predominate over the much slower initiation of secondary peroxidation propagation reactions by LOO· with vicinal unsaturated lipids ($k = 1.3 \times 10^3 M^{-1} s^{-1}$) (Leibler, 1994).

When inhibiting lipid peroxidation propagation reactions, NO undergoes an initial termination reaction with organic peroxyl radicals to form organic peroxynitrites (LOONO). During this overall reaction, two molecules of NO are consumed, because the original LOONO that is formed rapidly

decomposes ($t_{1/2} = 0.2\text{--}0.6$ s) to species that react with additional NO (O'Donnell *et al.*, 1997). Alternatively, the LOONO can hydrolyze to yield LOOH and NO₂⁻ (O'Donnell *et al.*, 1999b).

Nitric Oxide-α-Tocopherol Interactions in Lipid Oxidation

The body possesses endogenous protection mechanisms designed to prevent membrane and lipoprotein lipid oxidation, with the most widely recognized defensive molecule being vitamin E, and in particular the vitamin E isomer α-tocopherol. However, the often restricted location of α-tocopherol, especially in LDL, and poor bioavailability can constrain its effectiveness as a lipid antioxidant (Kayden and Traber, 1993; Dieber-Rotheneder *et al.*, 1991). Phenolic antioxidants such as α-tocopherol function through the donation of the hydrogen atom of a phenolic group to the peroxyl radical, to form a stable hydroperoxide [Eq. (3)]:

The kinetic efficiency of an antioxidant compound must be high, because propagation of lipid peroxidation, albeit slow ($k = 1.3 \times 10^3 M^{-1} s^{-1}$), is a self-sustaining reaction that may quickly overwhelm chain-breaking antioxidants. The first requirement of an effective lipid antioxidant is that the compound must react with LOO· faster than this propagating species can react with adjacent unsaturated fatty acids. It is important to note that this is a necessary but not sufficient condition for suppression of lipid peroxidation. Second, the reactions in which the newly formed antioxidant radical initiates further peroxidation or reconverts the LOOH to LOO· must be slow. By these criteria, α-tocopherol gives mixed results. First, the reaction of α-tocopherol with LOO· to yield the α-tocopheroxyl radical is not fast, occurring at a rate constant of $\sim 5 \times 10^5 M^{-1} s^{-1}$, with this rate affected by the alkyl chain length, degree of unsaturation, and esterified nature of the fatty acid undergoing peroxidation (Serbinova and Packer, 1994). Because of resonance stabilization of the phenoxyl radical and its potential subsequent rereduction by ascorbate, thiols, or enzyme-dependent mechanisms, the α-tocopheroxyl radical product has only limited capability to further propagate radical chain reactions under most biological conditions (Kagan and Packer, 1994).

Interestingly, on the basis of relative rate constants, it is predicted that in most biological conditions the reaction of ·NO with LOO· will predominate over both the reduction of LOO· by α-tocopherol and the initiation of secondary peroxidation propagation reactions by LOO· with vicinal unsaturated lipids. Thus, in tissues having an ambient concentration of 50 nM NO and 10–20 μM α-tocopherol, the efficiency of the two molecules in reacting with LOO· is approximately equal. When it is also considered that (a) NO is replenished by an enzymatic mechanism, (b) NO concentrates 20- to 30-fold in a lipophilic milieu, and (c) NO is freely diffusible and thus can terminate lipid and possibly

protein radical species with little or no regard to the spatial orientation of the radical intermediate within membrane or lipoprotein microenvironments, NO appears to be a more versatile antioxidant (O'Donnell *et al.*, 1997; Rubbo *et al.*, 2000).

Because the scavenging of LOO• results in the formation of an α -tocoperoxyl radical, its fate must also be considered. This is crucial, as the scavenging of propagating peroxy radicals is limited by the available number of electrons that can be channeled to the termination reaction. Physiologically, this problem is overcome through a series of redox shuttles that ultimately utilize cellular metabolism as the source of reducing equivalents (Buettner, 1993). An example of this type of mechanism is the recycling of the α -tocoperoxyl radical by ascorbate (Sato *et al.*, 1990). Under conditions where the lipid peroxidation reaction occurs in a compartment to which the ascorbate radical has restricted access, such as the lipid rich core of a lipoprotein, inhibition of peroxidation will be synergistic (Kalyanaraman *et al.*, 1992). In the case of NO, its activity as an antioxidant is coupled to the reducing equivalents in the cell (e.g., NADPH) that are required for NO synthesis by nitric oxide synthases (NOS). Thus, the level of antioxidant protection could be controlled in inflammatory sites by the availability and diffusion characteristics of NO.

It has been observed in more complex and multiple-antioxidant-containing oxidizing lipid systems that NO preferentially reacts with lipid radical species, with α -tocopherol consumption not occurring until •NO concentrations fell below a critical level (Rubbo *et al.*, 2000; Goss *et al.*, 1995). In addition, α -tocopherol and •NO cooperatively inhibited lipid peroxidation, exhibiting greater antioxidant capacity than the pair α -tocopherol/ascorbate. Pulse radiolysis analysis showed no direct reaction between •NO and α -tocoperoxyl radical, inferring that peroxy radical termination reactions were the principal lipid-protective mechanism mediated by •NO. These observations reaffirm the concept that •NO is a potent chain-breaking antioxidant toward peroxidizing lipids, via termination reactions with lipid radical species, thus preventing α -tocopherol loss. In comparison, the rereduction of α -tocoperoxyl radical by ascorbate was a comparatively less efficient mechanism for preserving α -tocopherol than •NO-mediated termination of peroxy radicals, owing to slower ascorbate- α -tocopherol and ascorbate-LOO• reaction kinetics and limited transfer of reducing equivalents from ascorbate in the aqueous phase.

Nitric Oxide Modulation of Enzymatic Lipid Oxidation Processes

Enzymatic oxidation products of unsaturated lipids activate signal transduction reactions via interaction with G-protein-coupled receptors. The best known oxidized lipid mediators are arachidonate-derived eicosanoids, including prostaglandins, thromboxanes, leukotrienes, and epoxides. These species are generated through oxidation reactions coordinated by prostaglandin endoperoxide H synthase

(PGHS), lipoxygenases (LOX), and cytochrome P-450 isoenzymes.

Generally, NO is inhibitory toward the enzymatic generation of oxidized lipid mediators. Because enzyme-catalyzed lipid oxidation products, especially hydroperoxide derivatives, can decompose through pro-oxidant and nonenzymatic propagation reactions, NO-mediated inhibition of lipid-oxidizing enzymes will ultimately result in limiting of both enzymatic and nonenzymatic lipid oxidation reactions. The inhibition of enzymatic lipid oxidation results from either (a) termination of lipid radical intermediates (LOX) or (b) formation of heme-nitrosyl complexes (cytochrome P-450). The exception to this paradigm is PGHS, where inhibition, activation, or no effect has been variously observed, depending on the cellular system examined.

PROSTAGLANDIN ENDOPEROXIDE H SYNTHASE

Prostaglandins (PG) are generated by PGHS, of which there are both constitutive (PGHS-1) and inducible (PGHS-2) isoforms. As a first step in catalysis, the enzyme oxidizes arachidonic acid to a cyclic endoperoxide, prostaglandin G₂ (PGG₂), by a cyclooxygenase activity, then a peroxidase reduces the peroxide to a hydroxide. This concerted catalytic event ultimately yields the endoperoxide prostaglandin H₂ (PGH₂) (Smith and De Witt, 1996). The peroxidase and cyclooxygenase activities of PGHS are separated by the heme prosthetic group and function independently of one another. Under inflammatory conditions, PGHS-2 expression is up-regulated by proinflammatory cytokines, which include interleukin-1 (IL-1) and tumor necrosis factor (Swierkosz *et al.*, 1995; Akarasereenont *et al.*, 1995; Vane *et al.*, 1994; De Witt, 1991; Davidge *et al.*, 1995). As these cytokines also induce inducible NOS (iNOS), high levels of both PG and NO will be produced together *in vivo*.

Reactive nitrogen species have multiple effects on PGHS. In assay systems, including purified PGHS-2, platelets, endothelial cells, and RAW 264.7 cells, and *in vivo*, in rats, NO potently stimulates PG production (Davidge *et al.*, 1995; Salvemini *et al.*, 1993, 1994; Manfield *et al.*, 1996). However, other investigators have found NO either to inhibit PGHS or to have no effect (Stadler *et al.*, 1993; Curtis *et al.*, 1996; Nakatsuka and Osawa, 1994). In contrast, for some cell types (rat microglial cells and peritoneal macrophages), NO suppresses LPS-induced PGHS-2 expression, resulting in apparent enzyme inhibition (Minghetti *et al.*, 1996; Habib *et al.*, 1997). Probable mitigating factors in these opposing outcomes, in addition to the manifestation of unique differentiated cell responses to NO, can include variations in NO concentration and underlying rates of oxidant production by cells.

Nitric oxide can interact with PGHS during turnover in several ways. These include formation of an iron-nitrosyl complex ($K_d = 0.92$ mM) (Tsai *et al.*, 1994), termination of the catalytic tyrosyl radical, reduction of compounds 1 and 2 of the peroxidase cycle, and possible termination of enzyme-bound lipid alkyl or peroxy radicals (Curtis *et al.*, 1996; Goodwin *et al.*, 1998; Gunther *et al.*, 1997). Following

reaction of NO with the heme, catalytic tyrosyl radical, or lipid radical intermediates, enzyme inhibition would be expected. However, NO reaction with compounds 1 and 2 would likely lead to enzyme activation. Intriguingly, a balance between inhibitory and activating effects of NO may also take place, as NO has little effect on the activity of purified PGHS (Curtis *et al.*, 1996). It has also been shown that ONOO⁻ is a peroxidase substrate for both PGHS isoforms (Landino, 1996). This suggests that ONOO⁻ could promote PG synthesis during inflammatory events, where accelerated rates of production of NO and O₂⁻ can be occurring.

LIPXYGENASES

Lipoxygenases are non-heme, iron-containing enzymes that oxidize polyenoic fatty acids, forming the corresponding lipid hydroperoxides. In mammalian systems, at least three isoforms are known. The best characterized, 5-LOX, is found in leukocytic cells (Ford-Hutchinson, 1994). 5-LOX generates precursors for the synthesis of leukotrienes, lipid products that stimulate a number of inflammatory and immune cell functions, including chemotaxis and aggregation, as well as playing central roles in inflammation and allergies. 12-LOX is found predominantly in platelets and monocytes. The *in vivo* activities of its product, 12(S)HPETE (12(S)hydroperoxyicosatetraenoic acid), are unknown, but *in vitro* studies show that it inhibits platelet aggregation (Brune *et al.*, 1991; Nyby, 1996). 15-LOX is highly expressed in reticulocytes during maturation, where it degrades intracellular membranes. Expression of 15-LOX can be induced in monocytes by IL-4 and IL-13 (Nassar, 1996; Conrad, 1992). The precise role of 15-LOX products are unknown,

but *in vitro* effects include stimulation of epidermal growth factor receptor signaling (Glasgow, 1997). A central role for 15-LOX in initiation and progression of atherosclerosis has been suggested by the observation that its products are found in atherosclerotic lesions (Kuhn, 1994, 1997; Folcik, 1995).

Lipoxygenases contain a single nonheme iron that cycles between Fe²⁺ and Fe³⁺ during turnover. Resting LOX is predominantly reduced and requires oxidation by hydroperoxides before dioxygenation can take place. Oxidation of arachidonate or linoleate is then catalyzed by the ferric enzyme as shown in Fig. 4.

Inhibition of several LOX isoforms (soybean, rabbit, and human 15-LOX, human platelet 12-LOX) by NO has been reported (Holzhutter, 1997; Weisner, 1996; Kanner, 1992; O'Donnell, 1996; Natasuka, 1994) and was originally suggested to be due to formation of an iron-nitrosyl complex with the ferrous enzyme. However, this species has been shown to be formed only at high NO concentrations, and thus its involvement in enzyme inhibition under biological conditions is unlikely (Rubbo, 1995; Nelson, 1987; Salerno, 1979; Galpin, 1978). More recent studies have shown that NO is consumed by LOX in a turnover-dependent manner. Also, LOX is inhibited only while NO is present. Mechanistic studies indicate that LOX inhibition is a result of a termination reaction between NO and the enzyme-bound lipid peroxyl radical (O'Donnell *et al.*, 1999b). Following this, dissociation and hydrolysis of the organic peroxynitrite (LOONO) forms LOOH and NO₂⁻ as products. To complete the catalytic cycle, reoxidation of the enzyme-bound iron is required. Since this is a slow process that proceeds at 20% of the rate of dioxygenation for the soybean 15-LOX, suppression of activity is observed.

Figure 4 Lipoxygenase-mediated fatty acid oxidation and the influence of NO. Three sites of potential NO reaction are shown: (i) During peroxide (LOOH) activation of LOX, 2 mol · NO are consumed, via reaction with an electron (e⁻) released from the ferrous enzyme (E_{red}) to form nitroxyl anion (NO⁻). Secondary reactions of NO⁻ will consume further ·NO. For example, reaction of NO⁻ with O₂ or with ·NO can occur as shown. (ii) During dioxygenase turnover, ·NO is consumed through reaction with E_{ox}LOO· to form reduced inactive enzyme (E_{red}) and an organic peroxynitrite (LOONO) that can be hydrolyzed to the hydroperoxide (LOOH) and nitrite (NO₂⁻). (iii) Finally, at higher ·NO concentrations, a ferrous nitrosyl complex may form (E-Fe²⁺-·NO) that slowly decomposes, yielding active enzyme (E*) (adapted from O'Donnell *et al.*, 1999b).

CYTOCHROME P-450

Cytochrome P-450 isozymes are a family of heme-containing enzymes that play central roles in xenobiotic metabolism and lipid oxidation reactions. Arachidonic acid oxidation by cytochrome P-450 occurs through three specific pathways, yielding a variety of oxygenated metabolites, including epoxides and fatty acid alcohols (Capdevila, 1992).

Nonhepatic cytochrome P-450-derived arachidonate metabolites act as intracellular signaling molecules in vascular tissue. The cytochrome P-450A product 20-hydroxyeicosatetraenoic acid (20-HETE) is a potent vasoconstrictor, produced in vascular smooth muscle cells (Harder, 1997). A second product, 11,12-epoxyeicosatetraenoic acid (11,12-EET), is produced by endothelial cells and becomes avidly esterified into endothelial phospholipid pools (Roslowski, 1996; Van Rollins, 1993). In several studies, EET species were observed to relax blood vessels, leading to the suggestion that EETs may account for (the so far unidentified) endothelial-derived hyperpolarizing factor (EDHF) (Roslowski, 1996). Finally, both thromboxane synthase and prostacyclin synthase, which metabolize the PGHS product PGH_2 to thromboxane A_2 (TXA_2) and prostacyclin (PGI_2), respectively, are cytochrome P-450 enzymes.

Several cytochrome P-450 isoenzymes are inactivated by NO. Activities that are inhibited include arachidonate hydroxylation to 20-HETE, testosterone hydroxylation, oxidation of *p*-nitrophenol and dimethylnitrosamine, generation of TXA_2 and PGI_2 , and O-ethylation of 7-ethoxyresorufin (Alonso-Garcia, 1997; Donato, 1997; Wink, 1993; Gergel, 1997; Minamiyama, 1997; Muller, 1996; Stadler, 1994). However, under some conditions generation of TXA_2 is actually stimulated by NO (Rosolowski and Campbell, 1996). The influence of NO on epoxide production by cytochrome P-450 has not been studied. However, $\cdot\text{NO}$ inhibits production of the hydroxylated arachidonate product, 20-HETE, by cytochrome P-450A in vascular smooth muscle cells. Since 20-HETE is a potent vasoconstrictor, this effect may contribute to vasodilatory effects of NO (Bolz *et al.*, 2000).

The Effect of Nitric Oxide on Oxidative Reactions Mediated by Heme Proteins

Peroxidase reactions are commonplace in biology, and both “professional” peroxidases and heme proteins that have “pseudoperoxidase” activity [e.g., myoglobin (Mb) or hemoglobin (Hb)] capable of oxidizing lipids *in vitro* are known (Gutteridge, 1987; Galaris *et al.*, 1990; Hogg *et al.*, 1994; Rogers *et al.*, 1995; Sarti *et al.*, 1994; Miller *et al.*, 1996; Paganga *et al.*, 1992; Ziouzenkova *et al.*, 1999; Kalyanaraman *et al.*, 1995). Their contribution to lipoprotein oxidation and atherosclerosis is unclear at present, but in support of a potential role, chlorination of tyrosine has been detected in atherosclerotic lesions. Also, the peroxidase capable of generating hypochlorite, myeloperoxidase, was also found (Daugherty *et al.*, 1994). The mechanism of heme

protein-dependent lipid peroxidation involves both initiation and propagation events. Initiation, by abstraction of a hydrogen atom from a polyunsaturated fatty acid, can be promoted by higher oxidation states of heme proteins such as the ferryl oxidation states of Hb or Mb, similar to complexes I and II of peroxidases (Galaris *et al.*, 1990; Miller *et al.*, 1996; Newman *et al.*, 1991; Dee *et al.*, 1991). Specific binding sites for fatty acids on the protein, as has been demonstrated for myoglobin, may facilitate these processes (Rao *et al.*, 1994). Similar to free transition metal ions, heme proteins can also catalytically decompose LOOH via a one-electron redox cycle that cycles between the ferric and ferryl oxidation states of Mb and Hb (Rogers *et al.*, 1995; Sarti *et al.*, 1994; Miller *et al.*, 1996).

Nitric oxide has been shown to inhibit heme protein-dependent oxidation of lipids via reduction of higher heme oxidation states. For example, NO rapidly reduces ferryl Mb to ferric Mb and can also terminate protein radicals associated with ferryl heme formation in complex I (Dee *et al.*, 1991; Kanner *et al.*, 1992; Gorbunov *et al.*, 1995). The precise role of such protein radicals in lipid peroxidation is not known, although initiation events have been suggested (Newman *et al.*, 1991). Finally, binding of NO to ferrous heme, a relatively rapid process, prevents redox cycling and formation of the higher oxidation states of heme required for heme-dependent lipid oxidation reactions to occur (Kanner *et al.*, 1991).

Nitric Oxide-Dependent Regulation of Antioxidant Enzymes

The direct reaction of NO with oxygen radicals can be a cytoprotective mechanism that will be most effective in situations that have a component of propagation in the reaction mechanism, such as lipid peroxidation. The cell signaling roles of NO are also critical in the context of maintaining a healthy vasculature and inhibiting the progression of inflammatory diseases such as atherosclerosis. The classic cell signaling pathway of NO, namely, the activation of soluble guanylate cyclase and formation of cGMP, occurs in vascular smooth muscle and platelets, representing important vasorelaxant and antithrombotic mechanisms (Moncada *et al.*, 1991). Inflammation, although a normal response to injury, also represents a key component of tissue damage that leads to the development of vascular disease. Modulation of cell signaling pathways in a cGMP-independent manner by NO includes inhibition of expression of cytokine-induced adhesion molecules [vascular cell adhesion molecule-1 (VCAM-1) and intracellular adhesion molecule-1 (ICAM-1)]. Binding of circulating leukocytes/monocytes to these integrins facilitates adherence and entrance of inflammatory cells into the arterial wall and thus represents a critical step in both vascular oxidant injury and atherosclerotic plaque development. The NO-mediated downregulation of inflammatory adhesion molecule expression includes inhibition of the

transcription factor NF- κ B (De *et al.*, 1995; Peng *et al.*, 1995) and represents an important indirect antioxidant action of NO.

Recent insights indicate that cGMP-independent NO signaling pathways are also capable of regulating transcriptional events that control the expression and synthesis of antioxidant enzymes (Moellering *et al.*, 1998, 1999; Li *et al.*, 1999; Frank *et al.*, 1999; Foresti *et al.*, 1997). The contrast in our understanding of these novel NO-signaling pathways compared to the cGMP-mediated actions of NO is interesting. In the case of the NO/cGMP pathway, a great deal is known about the upstream elements of the signaling cascade but relatively little about downstream events that regulate gene expression. In contrast, the downstream elements of the NO-mediated, cGMP-independent pathways are understood to some extent, but the upstream events and “receptor” for NO remains undefined. In this section these aspects will be discussed with particular reference to control of antioxidant enzyme expression.

One of the most important antioxidants in the cell is the small tripeptide glutathione (GSH), which plays an important role in the detoxification of reactive oxygen and nitrogen species (Deneke and Fanburg, 1989). For example, exposure of cells to exogenous oxidants or the endogenous formation of inorganic peroxides (e.g., ONOO⁻, H₂O₂), lipid peroxides, and their decomposition products (e.g., aldehydes and epoxides) is an unavoidable consequence of oxygen metabolism. The intracellular concentration of these species, whether playing a role in cell signaling or cytotoxicity, is controlled by an integrated network of metabolic enzymes and antioxidants. Glutathione, in its reduced form, is an enzyme cofactor capable of reducing cell protein thiols, enzymatic reduction and undergoing direct reaction with reactive oxygen and nitrogen species. The intracellular concentration of GSH is typically 1–5 mM; its actions and the steps leading to its synthesis (Deneke and Fanburg, 1989) are summarized in Fig. 5.

In situations of acute NO-mediated oxidative stress on activation of iNOS, induction of GSH synthesis occurs to maintain adequate levels of the antioxidant, since inhibition of NOS activity causes GSH levels to fall precipitously (Kuo *et al.*, 1996). This is most likely a mechanism specific to the pleiotropic stimulus of cytokine treatment. Under physiological conditions, both endothelial and vascular smooth muscle cells exposed to NO at low fluxes are stimulated to synthesize additional GSH (Moellering *et al.*, 1998, 1999).

A recent addition to the family of antioxidant enzymes is heme oxygenase. Heme is widespread throughout the cell and plays a critical role in electron transfer reactions, cell signaling, and oxygen transport (Foresti and Motterlini, 1999). The capacity of the iron in the heme molecule to promote oxidative reactions also makes heme proteins a potential source of toxicity. One of the most important detoxification pathways of free heme is the enzyme heme oxygenase (HO), which catalyzes the decomposition of heme, in turn yielding carbon monoxide and biliverdin as by-products. The further metabolism of biliverdin forms bilirubin,

Figure 5 The synthesis of GSH and its interaction with NO. The first step of GSH synthesis, formation of γ -glutamylcysteine by γ -glutamylcysteine synthetase, is rate limiting. The activity of γ -glutamylcysteine synthetase is modulated by pro-oxidants (e.g., H₂O₂) and by nonoxidative mechanisms related to cell density and the availability of glutamate. In the final step of GSH biosynthesis, glycine is incorporated by GSH synthetase. The uptake of the amino acids cystine and methionine are also important in controlling GSH levels.

which also has potent antioxidant properties (Maines, 1988). Carbon monoxide has been associated with cytoprotective effects through mechanisms that have not yet been defined but may include NO-mediated mechanisms (Vercellotti *et al.*, 1994; Thom *et al.*, 2000). One possible explanation is the tight binding of CO to ferrous heme, retarding oxidation to the more pro-oxidant ferrous or ferryl forms of the heme molecule. Of course free iron is also a by-product of this reaction, but relative to heme this is readily sequestered by proteins in the cell and is of limited potential to promote pro-oxidant reactions. Heme oxygenases manifest antioxidant properties through several different mechanisms. The enzyme exists in two isoforms, HO-1 (inducible) and HO-2 (constitutive). Heme oxygenase-1 is induced by a wide variety of toxic stimuli, including free heme. It is not clear whether induction involves oxidant-dependent loss of heme from endogenous proteins or is mediated by an independent signaling pathway. Several studies have convincingly shown that this enzyme is capable of protecting against both oxidative and nitrosative stress (Vercellotti *et al.*, 1994; Applegate *et al.*, 1991).

More recent investigations have revealed a potentially important interaction between heme metabolism and NO, via HO-1 (Juckett *et al.*, 1998). Exposure of diverse cell types to NO, including hepatocytes and aortic endothelial cells, results in induction of HO-1. The concentrations of NO needed to elicit these effects are difficult to estimate from the data presented, but they are certainly higher than levels obtained from endothelial NOS (eNOS) activation and more closely relate to those achieved from iNOS. More detailed studies have shown that the mediator involved could be ONOO⁻, an observation consistent with the higher levels of NO required to elicit increased HO-1 activity (Foresti *et al.*, 1997). The signal transduction pathway is cGMP-

independent and results in both increased transcription and the stabilization of the mRNA for HO-1.

Summary

Chemical, cell biological, and *in vivo* studies all reveal that NO has the capacity to serve a tissue-protective role in inflammatory diseases that have oxidative injury as a component. In some conditions, for example, a microenvironment rich in O_2^- , NO will also amplify oxidant injury via ONOO⁻ formation. In other instances, when a different milieu of inflammatory mediators is present, NO is capable of terminating radical reactions and limiting overall oxidative tissue injury via overriding competing influences. Because of the diverse reaction pathways and signaling events in which reactive species are capable of participating, it is not practical to ascribe a singular "antioxidant" property to NO. Present understanding of the multifaceted tissue-protective actions of NO suggest that (a) NO-mediated stimulation of expression of antioxidant defenses (e.g., GSH biosynthesis), (b) protection of membranes and lipoproteins from oxidation, and (c) inhibition of production of inflammatory mediators (cytokines, eicosanoids, and integrin synthesis/expression) all contribute to the limitation of inflammatory injury to tissues by $\cdot NO$.

Mechanisms through Which Reactive Nitrogen and Oxygen Species Interact with Physiological Signaling Systems

Michael S. Wolin

Department of Physiology

New York Medical College

Valhalla, New York

NITRIC OXIDE (NO), REACTIVE OXYGEN SPECIES (ROS), AND REACTIVE NITROGEN SPECIES (RNS) DERIVED FROM NO HAVE MULTIPLE INTERACTIONS WITH CELLULAR CONTROL MECHANISMS THAT RANGE FROM FUNDAMENTAL SIGNALING PROCESSES TO SENSING SYSTEMS FOR THE LEVELS OF INDIVIDUAL ROS AND RNS. SOME OF THE MOST POTENT EFFECTS OF NO ARE ITS INTERACTIONS WITH HEMOPROTEINS IN PROCESSES INCLUDING THE STIMULATION OF SOLUBLE GUANYLATE CYCLASE (sGC), THE INHIBITION OF CYTOCHROME OXIDASE, AND THE INACTIVATION OF NO BY HEMOGLOBIN. THE METABOLISM OF PEROXIDE BY ENZYMES INCLUDING CATALASE, HEME PEROXIDASES, AND GLUTATHIONE PEROXIDASE RESULTS IN THE ACTIVATION OF SENSITIVE SIGNALING MECHANISMS FOR ROS INCLUDING THE STIMULATION OF sGC, PROSTAGLANDIN FORMATION, AND THIOL REDOX-REGULATED PROCESSES, RESPECTIVELY. THE REACTION OF NO WITH SUPEROXIDE ACTIVATES ADDITIONAL SIGNALING MECHANISMS VIA THE FORMATION OF PEROXYNITRITE AND OTHER RNS BY PROCESSES INCLUDING MODIFICATION OF IRON-SULFUR CENTERS AND THIOL NITROSATION, NITRATION, AND OXIDATION. MANY ADDITIONAL REGULATORY PROCESSES SEEM TO RESULT FROM INTERACTIONS BETWEEN NO AND ROS SIGNALING SYSTEMS AND FROM THE PERTURBATION OF ANTIOXIDANT DEFENSE MECHANISMS. THUS, THE INTERACTIONS OF RNS AND ROS WITH SIGNALING SYSTEMS HAVE EVOLVED INTO MULTIPLE REGULATORY ROLES IN PHYSIOLOGICAL SYSTEMS AND PATHOPHYSIOLOGICAL PROCESSES.

Introduction

This chapter focuses on examining how the physiological chemistry and enzymatic interactions of reactive species derived from nitric oxide (NO) and the reduction of oxygen are

incorporated into fundamental cellular signaling mechanisms. Emphasis will be placed on processes involving reactive nitrogen species (RNS) and reactive oxygen species (ROS) that do not appear to be associated with conditions which result in irreversible cellular injury and dysfunction.

Several of the preceding chapters of this book have considered important aspects of the production of NO, the metabolism of NO, and the chemical reactivities and properties of key RNS. The chemical properties of RNS and ROS have been extensively investigated. Components of physiological systems such as antioxidant defense mechanisms have a major role in controlling the species that are present. The interactions of certain RNS and ROS with enzymes and other components result in the formation of additional reactive intermediates that often participate in the sensing of these species and activation of signaling processes. Thus, it is important to consider which RNS and ROS are present in physiological systems in amounts that are linked to the activation of signaling processes discussed in subsequent sections of this chapter and to consider how metabolic interactions of these species could be linked to their detection.

Roles for NO-Derived Species in Physiological NO Detection Mechanisms

In this section, the NO-derived species that potentially form in the absence of an interaction with ROS are discussed. Consideration of the species that form as a result of interactions of NO with ROS is a very important aspect of this topic, which is evaluated later in this chapter.

NO–Heme Species

The binding of NO to the Fe^{2+} or ferrous form of heme groups on proteins is one of the most potent actions of NO. However, many of the hemoproteins in cells have their heme stabilized in a higher oxidation state, such as the ferric or Fe^{3+} form, or have the heme group sequestered by the structure of the protein in a manner that prevents the binding of NO. Some hemoproteins have the iron of their heme groups entering oxidation states higher than Fe^{3+} (such as ferryl or Fe^{4+} , and species termed compound I and II) as transient intermediates in their catalytic reaction. NO can also function as an electron donor to heme groups in higher oxidation states. This can attenuate oxidation reactions catalyzed by the hemoprotein (Wink *et al.*, 1995). NO also seems to have the ability to reduce Fe^{3+} heme to its Fe^{2+} form when present at very high levels (Keilin and Hartree, 1937).

GUANYLATE CYCLASE

Activation of the soluble form of guanylate cyclase (sGC) is known to occur at low nanomolar concentrations of NO as a result of NO binding its Fe^{2+} -heme forming a Fe-NO species (Ignarro, 1989). The binding of NO to the heme results in enzyme activation as a result of NO causing the scission of the histidine bond to the Fe^{2+} of the heme (Deinum *et al.*, 1996; Yu *et al.*, 1994). Although the formation of NO–heme on sGC has been suggested to cause oxidation of the heme to its Fe^{3+} form (Dierks and Burstyn, 1998), other studies

indicate that the binding of NO is reversible, and the regeneration of the Fe^{2+} as a result of the dissociation of NO is a process involved in the termination of enzyme stimulation (Kharitonov *et al.*, 1997). Some of the inhibitors of sGC stimulation, such as methylene blue (Dierks and Burstyn, 1998) and ODQ (1*H*-[1,2,4]oxadiazolo[4,3-*a*]quinoxalin-1-one) (Schrammel *et al.*, 1996), seem to attenuate sGC stimulation by oxidizing the NO– Fe^{2+} -heme complex to its Fe^{3+} form, which appears to be resistant to stimulation by NO. Evidence suggests that an NADPH-dependent oxidoreductase may control the redox state of the heme of sGC and that this may be an important component of the sensitivity of sGC in tissues to activation by NO (Gupte *et al.*, 1998). Aspects of the mechanism of activation of sGC by NO are described in detail in other chapters of this book.

CYTOCHROME OXIDASE

At low concentrations NO binds the heme–copper centers of cytochrome oxidase through an interaction that is thought to involve both of these centers (Torres *et al.*, 1998). As discussed in greater detail later in this chapter, the binding of NO to this site results in a reversible inhibition of mitochondrial electron transport (Brown *et al.*, 1997). An interesting aspect of the binding of NO to cytochrome oxidase is that it appears to have a competitive interaction with molecular oxygen (Brown *et al.*, 1997). A competition of this type suggests that NO could function in a manner which shifts the range of mitochondrial sensing of oxygen from the nanomolar concentrations normally seen in isolated mitochondria up into the micromolar range, which has often been observed in tissue spectroscopy studies (Jobsis, 1972). It has been reported that cytochrome oxidase can metabolize NO to N_2O (Brown *et al.*, 1997). However, there is little evidence suggesting that cytochrome oxidase is an important site for the metabolism of NO in tissues (Stubauer *et al.*, 1998).

CATALASE

Catalase is an important metabolizing system for hydrogen peroxide (H_2O_2) (Chance *et al.*, 1979) and a key participant in the stimulation of sGC by H_2O_2 (Burke and Wolin, 1987; Cherry and Wolin, 1989). Evidence exists for interactions of NO with the heme of catalase that result in the observation of both reversible and irreversible inhibition of this enzyme. The reversible inhibition of catalase appears to be associated with a reversible binding of NO to the heme of the enzyme (Brown, 1995). In contrast, under conditions where an irreversible inhibition of catalase has been observed, a species resembling the inactive compound II of catalase has been detected (Mohazzab-H. *et al.*, 1996). Compound II is thought to be a ferryl heme-containing form of catalase and appears to be a relatively stable, inactivated form of this enzyme. Although little is known regarding how NO functions in tissues as an inhibitor of catalase, it has been observed that levels of NO which cause the formation of peroxynitrite in vascular tissue (a 2-min exposure to 50 nM NO) result in a prolonged inhibition of catalase activity (Wo-

lin *et al.*, 1998). Thus, under conditions where NO inhibits catalase, it will function to impair the metabolism of peroxide and prevent the stimulation of sGC by H_2O_2 . This action of NO has been observed in vascular tissue (Mohazzab-H. *et al.*, 1996).

CYTOCHROME P-450

NO has been demonstrated to inhibit the metabolic activities of cytochrome P-450 through what appears to be a reversible binding of NO to its heme group and through an irreversible process caused by RNS (Wink and Mitchell, 1998). The metabolism of arachidonic acid by cytochrome P-450 is a pathway for the formation of eicosanoids that have important roles in intracellular and transcellular signaling processes. Evidence suggests that NO appears to function in endothelium as an inhibitor of the formation of mediators by cytochrome P-450, where the loss of NO production results in the generation of cytochrome P-450-derived vasoactive eicosanoids (Sun *et al.*, 1998).

CYCLOOXYGENASE AND PROSTAGLANDIN METABOLISM

Since NO has been observed to have both stimulatory and inhibitory actions on production of prostaglandins in intact cells and tissues, there has been much interest in how NO influences the activity of cyclooxygenase (COX) and prostaglandin-metabolizing enzymes. It has been shown that NO reacts with a tyrosyl radical formed during the cyclooxygenase reaction, causing an irreversible inhibition of this enzyme as a result of nitrotyrosine formation (Goodwin *et al.*, 1998). Oxidized products of NO may also influence prostaglandin metabolism. The regulation of COX and prostaglandin metabolism by NO mechanisms is further discussed later in this chapter.

HEMOGLOBIN AND MYOGLOBIN

NO has an extremely potent interaction with the oxygen-bound heme of proteins including hemoglobin and myoglobin. NO reacts with $Fe^{2+}-O_2$ forms of these proteins at what appear to be diffusion controlled reaction rates, producing the Fe^{3+} forms of the hemoproteins and nitrate (Doyle and Hoekstra, 1981). While this process is clearly very important in signaling as a result of its terminating the biological actions of NO *in vivo*, formation of the methemoproteins and nitrate is not known to be associated with activation of additional signaling processes. It is difficult to detect the oxidation of hemoglobin by NO in erythrocytes because of the extremely efficient actions of methemoglobin reductase activity present in these cells (Hultquist, 1978). Hemoglobin-like proteins have the potential to promote pathophysiological responses as a result of their ability to cooxidize biological constituents such as lipids through peroxidase reactions. NO may function as an antioxidant by attenuating these processes as a result of its ability to reduce the higher oxidation states of iron (e.g., ferryl or Fe^{4+}) that catalyze these reactions (Wink *et al.*, 1995).

NO–Iron Species

The formation of $(RS)_2Fe(NO)_2$ complexes have been observed in tissues at what appears to be high nanomolar to low micromolar levels of NO (Hibbs *et al.*, 1990; Mulsch *et al.*, 1993). These NO complexes are potentially linked to several different signaling mechanisms. First, one needs to consider where the iron came from and what the consequence of its removal might be. NO has been reported to release iron by disrupting iron–sulfur centers on proteins such as aconitase and complexes I and II in the mitochondrial electron transport chain (Hibbs *et al.*, 1990). While damage to the iron–sulfur centers is generally considered an irreversible processes which would be beyond the scope of this chapter, evidence exists that there may be iron-dependent mechanisms of repair for iron–sulfur centers that are damaged by NO (Hibbs *et al.*, 1990). As is considered later in this chapter, the removal of iron from iron–sulfur centers would cause a prolonged inhibition of mitochondrial electron transport. NO also causes a loss of iron from the cytosolic aconitase, converting this enzyme into a form of the iron responsive binding protein (Drapier and Bouton, 1996). Under conditions where peroxynitrite forms, the iron responsive binding protein lacks its normal ability to bind and activate the iron responsive element system, and this prevents activation of the expression of the transferrin receptor and of downregulation of ferritin production, which would normally promote an increase in cellular iron uptake. This action of NO on cellular iron metabolism may be more of a protective antioxidant effect than a signaling mechanism. The availability of iron could be a process that indirectly affects signaling as a result of its influencing the release of iron and the formation of $(RS)_2Fe(NO)_2$ complexes. These Fe–NO complexes also are likely to serve both as tissue storage forms of NO and as a chelated form of iron that is potentially resistant to participation in oxidant stress-induced cellular injury.

NO–Thiol Species

There is substantial evidence that the nitrosation of thiols occurs in tissues (Gaston *et al.*, 1994; Stamler *et al.*, 1992). However, the actual process involved in nitrosation seems rather poorly understood. Iron–NO species related to $(RS)_2Fe(NO)_2$ complexes have been demonstrated to generate nitrosated thiols or thionitrites (RSNO) in the presence of physiological levels of thiols (Boese *et al.*, 1995). It has also been suggested that oxidation reactions of species formed from the reversible binding of NO to thiols result in the formation of RSNO (Gow *et al.*, 1997). Although these mechanisms appear to form RSNO species, there may be some more sensitive mechanisms for the formation of RSNO species under physiological conditions. As discussed later in this chapter, oxidation products of NO are potentially a physiologically relevant source of $RSNO_x$ species (Davidson *et al.*, 1997). Once RSNO species are formed, they may

function in transnitrosation reactions, which would transfer the NO group to thiols that have enhanced chemical reactivities, and this could be a component of a regulatory mechanism (Arnette and Stamler, 1995). Some of the systems potentially regulated by thiol nitrosation-related processes are considered later in this chapter.

Mechanisms of Detection of ROS by Physiological Signaling Systems

Signaling mechanisms through which ROS can be detected are discussed here in a manner that permits consideration, later in this chapter of how NO and its metabolites interact with the individual ROS and with the systems they appear to regulate. Signaling mechanisms for ROS have been the subject of several reviews (Wolin, 1996; Wolin *et al.*, 1996, 1999a; Lander, 1997; Suzuki *et al.*, 1997; Wolin and Mohazzab-H., 1997; Abe and Berk, 1998).

Control of the Production and Levels of ROS

Cells appear to have basal sources of ROS production and signaling mechanisms. Pathophysiological states often activate ROS production by additional systems. Tissues contain oxidase enzymes that transfer electrons to oxygen resulting in the production of ROS. Most of the enzymes that reduce oxygen donate one electron to molecular oxygen, producing superoxide anion. Although superoxide readily reacts with itself at physiological pH, the enzyme superoxide dismutase (SOD) markedly accelerates the conversion of superoxide to H_2O_2 and molecular oxygen. In animal tissues there are three forms of SOD. SOD-1 is a Cu,Zn-containing form of SOD that is found in the cytosol of most cells. SOD-2 is a Mn form of SOD present in the mitochondrial matrix. SOD-3 is an extracellular Cu,Zn-SOD that is bound to the matrix of certain tissues (Oury *et al.*, 1994). It is important to note that the level of SOD activity is a major regulator of the reaction of NO with superoxide, an interaction that appears to result in the activation of signaling mechanisms considered later in this chapter. Most of the H_2O_2 present in tissues that appears to participate in signaling mechanisms seems to originate from systems that produce superoxide anion and from the metabolism of superoxide by SOD (Wolin and Mohazzab-H., 1997). Catalase, glutathione (GSH) peroxidase, and heme peroxidase enzymes are the major cellular metabolizing systems for H_2O_2 in most tissues (Chance *et al.*, 1979). Many of the signaling mechanisms linked to peroxide appear to originate from its metabolism by these enzymes. The reaction of peroxide with hemoproteins or certain chelated forms of Fe^{2+} result in the generation of species that have chemical reactivities similar to the extremely reactive hydroxyl radical. Although these hydroxyl radical-like species are likely to be participants in tissue injury, some of these species may have the potential to initiate signaling processes through oxidation reactions that they promote.

ROS GENERATION BY MITOCHONDRIA

Mitochondria normally produce superoxide anion in amounts that appear to be relatively small compared to the rates of oxygen reduction to H_2O by the cytochrome oxidase reaction. Under normal circumstances it seems that mitochondria release only a small amount of the ROS that they produce, and due to the high levels of MnSOD present, the primary species that they appear to release is H_2O_2 . Two major sites of superoxide production have been located in the complex I (NADH dehydrogenase) and coenzyme Q_{10} segments of the electron transport chain. These sites produce superoxide in a manner that seems to be primarily dependent on the availability of electrons or degree of reduction of these sites, suggesting that superoxide anion production might be increased in resting states. Although little is known regarding the regulatory role of the basal production of ROS by mitochondria, studies have provided evidence that mitochondrial superoxide could have an important influence on the interaction of NO with mitochondrial respiration and perhaps apoptosis (Poderoso *et al.*, 1998; Wallace, 1999).

ROS GENERATION BY NAD(P)H OXIDASES

Tissues contain several different NADPH and NADH oxidases that are potentially linked to signaling processes.

NADPH Oxidases Phagocytic cells contain a NADPH oxidase whose activity is controlled by signaling pathways associated with activation of these cells (Thelen *et al.*, 1993). Although substantial evidence is accumulating suggesting that the components of the phagocytic NADPH oxidase are present in other cell types (Cross and Jones, 1991; Griending and Ushio-Fukai, 1997), only minimal information is available on the function of this system in these other cell types. Cytochrome P-450 and cytochrome P-450-like enzymes such as NO synthase (NOS) appear to be able to generate superoxide from NADPH at their heme site in a manner that may be of relevance to physiological signaling processes. For example, the depletion of tetrahydrobiopterin has been shown to change the endothelium-derived relaxant mediator generated by porcine coronary endothelium from NO to H_2O_2 (Cosentino and Katusic, 1995), through a process that appears to originate from the role this cofactor has in controlling electron transfer in the NOS reaction (Rusche *et al.*, 1998). Substrates for cytochrome P-450 enzymes also seem to have a major influence on promoting and inhibiting superoxide generation by this system. The flavin sites of cytochrome P-450 reductase may also contribute to the generation of oxidant species when redox cycling agents or metals such as iron are available as electron acceptors (Cenas *et al.*, 1994). It appears that the various types of NADPH oxidases discussed here will have important roles in signaling when these systems are producing oxidant species.

NADH Oxidases Although early investigations of the sources of ROS production in tissues detected a prominent role for NADH oxidase activity (Chance *et al.*, 1979), this activity was only relatively recently recognized as a poten-

tially important system that could be linked to physiological control mechanisms (Griendling and Ushio-Fukai, 1997; Wolin *et al.*, 1999b). It was initially observed that cellular growth factors regulated NADH oxidase activity (Morre and Brightman, 1991), and evidence supporting the significance of this system in the control of this process is accumulating (Griendling and Ushio-Fukai, 1997). Observations on the effects of lactate and pyruvate on vascular tissue resulted in the hypothesis that the redox status of cytosolic NAD(H) could have a major influence on the production of vasoactive ROS by NADH oxidase (Omar *et al.*, 1993; Wolin *et al.*, 1996; Wolin *et al.*, 1999b). Evidence has continued to accumulate supporting the concept that cytosolic NAD(H) redox and NADH oxidase-derived ROS have important roles in mechanisms that control vascular function (Wolin *et al.*, 1999b). It appears that the behaviors of the glycolytic enzymes that produce and metabolize NADH and of the mitochondrial shuttle mechanisms that import NADH into the mitochondria are basic cellular processes designed to keep the redox status of cytosolic NAD(H) in a highly oxidized state (Rabinowitz *et al.*, 1998). Thus, the availability of cytosolic NADH is potentially an important process that controls oxidant signaling mechanisms. As the production of superoxide by NADH oxidase appears to increase over the range of oxygen levels that typically exist in physiological systems (Mohazzab-H. and Wolin, 1994), the availability of oxygen as a substrate for NADH oxidases is potentially an additional important aspect of the way this system functions. Evidence appears to be rapidly accumulating in multiple cell types suggesting that NAD(P)H oxidases are important sources of basal oxidant production linked to signaling processes controlling cellular function. The dependence of the activity of NADH oxidase on the availability of cytosolic NADH and oxygen may enable this system to function as a key cellular metabolic and oxygen sensor, in addition to its potential role in receptor regulated oxidant signaling processes.

OTHER SOURCES OF ROS PRODUCTION

Cyclooxygenase and xanthine oxidase are other sources of production of ROS, and they appear to generate these species in amounts that have been observed to alter signaling processes. Cyclooxygenase is the initial enzyme in the pathway that produces prostaglandins, and it seems to be found in a wide variety of cell types. The catalytic mechanism of COX appears to produce ROS by causing a one-electron oxidation of cofactors such as NAD(P)H. This results in the generation of a free radical intermediate form of NAD(P) that reduces oxygen to superoxide anion (Kukreja *et al.*, 1986). Cyclooxygenase has been demonstrated to be a significant source of vasoactive ROS in the cerebral microcirculation (Marshall and Kontos, 1991). It appears that bradykinin receptor-mediated stimulation of prostaglandin production in endothelium results in the simultaneous generation of superoxide anion (Holland *et al.*, 1990). Xanthine dehydrogenase/oxidase is an enzyme localized primarily in the vascular endothelium. It appears that the oxidase activity of xanthine dehydrogenase is increased by thiol oxidation or

proteolysis of the enzyme under multiple pathophysiological conditions such as ischemia–reperfusion (Granger, 1988). Although other sources of ROS production have been observed, including H_2O_2 -generating enzymes in peroxisomes (Chance *et al.*, 1979), these other sources have not been linked to the production of ROS in tissues in amounts that appear to regulate signaling mechanisms.

CONTROL OF SUPEROXIDE ANION LEVELS AND H_2O_2 PRODUCTION BY SOD

The activity of each of the three major types of SOD appears to have a considerable role in controlling the local levels of superoxide anion and the interactions between superoxide and signaling mechanisms. This is because the local activity of SOD influences the distribution of ROS that are present, and each oxygen-derived species has its own interactions with signaling systems. Superoxide anion normally reacts with itself to form oxygen and H_2O_2 . SOD functions as a catalyst to markedly accelerate this process. The rate constants indicate that SOD has a reaction rate with superoxide that is $2 \times 10^9 \text{ M}^{-1} \text{ s}^{-1}$ compared to the rate of $8 \times 10^4 \text{ M}^{-1} \text{ s}^{-1}$ for the reaction of superoxide with itself (Fridovich, 1985). It is important to keep in mind that the efficiency of SOD is also directly dependent on the amount of SOD activity present. Thus, SOD activity is typically low in the extracellular environment, unless appreciable levels of SOD-3 are present. In contrast, SOD-1 and SOD-2 levels are generally quite high in the intracellular environment of cells, and this results in the presence of intracellular levels of superoxide in the picomolar range (Fridovich, 1985), which are likely to be substantially below the concentrations that appear to influence known signaling processes. However, since the rate of reaction of superoxide with NO of $7 \times 10^9 \text{ M}^{-1} \text{ s}^{-1}$ is three times its reaction rate with SOD, elevated levels of NO can compete with SOD for the scavenging of superoxide, and this enables superoxide to influence signaling processes (see later) through the generation of peroxynitrite. Thus, the local levels of SOD directly control the extent to which superoxide interacts with NO and other systems that metabolize superoxide.

PEROXIDE METABOLIZING SYSTEMS AND THE CONTROL OF H_2O_2

Peroxide metabolizing enzymes including catalase, GSH peroxidase, and heme peroxidases, appear to have two major roles in oxidant signaling mechanisms. They control the cellular levels of peroxides, and the metabolism of peroxide by these enzymes is linked to several of the most sensitive signaling processes. Under normal circumstances, these peroxide-metabolizing systems are thought to keep the intracellular levels of H_2O_2 in the high picomolar to low nanomolar concentration range (Chance *et al.*, 1979).

Catalase Catalase is a hemoprotein that metabolizes H_2O_2 to water and oxygen through the formation of an intermediate of catalase termed compound I, in a manner that does not require the presence of electron donors or acceptors.

Although catalase activity is markedly enriched in peroxisomes, there is substantial evidence that its activity is present in the cytosol and possibly other cellular organelles. Catalase has the ability to cometabolize other substances, typically resulting in a two-electron oxidation of the substance by the compound I intermediate of catalase. Although little is known regarding which cellular constituents are cometabolized by catalase, it is likely that tissues contain substances which serve as electron donors to catalase. When compound I of catalase reacts with a one-electron donor, it forms a compound II intermediate, which is a rather stable inactivated form of catalase. It is important to note that both superoxide and perhaps NO appear to serve as one-electron donors to catalase (Brown, 1995; Kono and Fridovich, 1982). As previously mentioned, the metabolism of peroxide by catalase has been demonstrated to promote activation of the production of cGMP by sGC. Both superoxide and NO have been demonstrated to inhibit the H_2O_2 -elicited cGMP-associated relaxation responses in vascular preparations (Cherry *et al.*, 1990; Mohazzab-H. *et al.*, 1996). Thus, catalase is important both in controlling tissue peroxide levels and in promoting the activation of sGC when it is metabolizing H_2O_2 , and species such as NO and superoxide appear to be important, physiologically relevant inhibitors of these actions of catalase.

GSH Peroxidase One of the most important systems for the metabolism of H_2O_2 are GSH peroxidase enzymes. This enzymatic activity is often the most prominent peroxide metabolizing system present in cells. GSH peroxidase activity is a primary metabolic pathway for peroxide consumption in both the cytosol and mitochondria (Chance *et al.*, 1979). The function of GSH peroxidases appears to be directly dependent on the concentration of GSH, and GSH is used to reduce H_2O_2 to water. Tissue GSH levels are typically in the low millimolar concentration range, and GSH is maintained in its reduced state by the high levels of NADPH-dependent GSH reductase activity present in tissues. The consumption of peroxide by GSH peroxidase is linked to metabolism through the regeneration of NADPH by systems such as glucose metabolism through the pentose phosphate pathway. An elevation in the amount of peroxide in tissues causes increases in the levels of oxidized GSH (GSSG) under conditions where the rate of production of GSSG exceeds its rate of removal. The increase in GSSG levels appears to promote a stimulation of signaling as a result of enzyme-catalyzed formation of disulfides of GSH with protein thiols [S-thiolation (RSSG)]. As superoxide (Blum and Fridovich, 1985) and peroxynitrite (Asahi *et al.*, 1995) appear to inhibit GSH peroxidase activity, high levels of production of these species are likely to promote increases in peroxide levels as a consequence of the inactivation of GSH peroxidase activity. Thus, GSH peroxidase is important both in controlling tissue peroxide levels and in promoting signaling by providing GSSG for S-thiolation-type modifications of proteins.

Heme Peroxidases The heme peroxidases detected in mammalian tissues seem to be present in amounts that are significantly less than the other peroxide metabolizing sys-

tems, suggesting that they are designed more to function in signaling mechanisms controlled by peroxide levels than to have a significant role in the control of cellular peroxide levels. However, the heme peroxidases found in phagocytic cells (such as myeloperoxidase) are present in amounts sufficient to be a significant source of cellular peroxide consumption. The purpose of these peroxidases appears to be the generation of ROS (such as hypochlorous acid), which are more reactive than H_2O_2 , for use in phagocytic cell defense mechanisms. Whereas several hemoproteins in cells have been demonstrated to have heme peroxidase activity, COX appears to be the only enzyme other than the phagocytic cell peroxidases that has been documented to express this activity under physiological conditions.

Interactions of Superoxide Anion with Signaling Systems

Superoxide anion appears to have several interactions with cellular signaling systems. The most sensitive mechanism seems to originate from the ability of elevated levels of NO to function as a scavenger of superoxide in competition with the SOD reaction. The signaling aspects of this process that generate peroxynitrite are considered later in this chapter. As superoxide production increases and/or the activity of SOD becomes impaired, superoxide will begin to scavenge NO in both the extracellular and intracellular environment in tissues. If NO levels are relatively low, the amount of peroxynitrite that forms may not be sufficient to interact with other signaling systems. An elevation of tissue superoxide levels has been demonstrated to inhibit vascular relaxation to H_2O_2 , which appears to be a result of sGC stimulation by catalase-mediated peroxide metabolism, suggesting that catalase activity in tissues can be inhibited by elevated levels of superoxide (Cherry *et al.*, 1990). The iron-sulfur center of aconitase appears to be a target for superoxide, and an inactivation of this enzyme is known to result in an impairment of mitochondrial function (Gardner *et al.*, 1994). It is well documented that superoxide can inactivate aconitase in intact tissues, and observation of an inactivation of aconitase has been used as a method of detection of elevated levels of intracellular superoxide anion. Elevated levels of superoxide are thought to reductively release iron from iron-sulfur centers and from ferritin. Reactions of the iron that is released with other ROS or RNS may result in the modulation of other signaling processes or the initiation of tissue injury (Wink and Mitchell, 1998). The regulatory actions of both NO and catecholamines such as epinephrine and norepinephrine are very sensitive to disruption by superoxide in the extracellular environment, where there is often low SOD activity; as a result, these regulatory substances have extremely high rates of reaction with superoxide (Abrahamsson *et al.*, 1992; Wolin and Belloni, 1985).

Interactions of H_2O_2 with Signaling Systems

In this section the processes through which H_2O_2 interacts with signaling systems are discussed with a focus on provid-

ing background for considering how NO and its metabolites interact with these systems. It is important to keep in mind that the activity of peroxide metabolizing systems, which have a significant influence on H_2O_2 concentrations, will modulate the expression of all of the other peroxide signaling systems as a result of controlling the levels of H_2O_2 .

SYSTEMS LINKED TO THE METABOLISM OF PEROXIDE BY CATALASE—REGULATION OF sGC ACTIVITY

The activation of sGC by H_2O_2 metabolism by catalase has been examined both with purified enzymes and in intact vascular tissue (Burke and Wolin, 1987; Cherry and Wolin, 1989), demonstrating the potential physiological significance of this process. The stimulation of sGC appears to require a continuous rate of H_2O_2 metabolism by catalase and levels of peroxide in the high picomolar to low nanomolar range, which cause the formation of the compound I species of catalase. The function of this mechanism appears to be extremely dependent on the presence of tissue SOD activity, because it is very susceptible to inhibition by superoxide (Cherry *et al.*, 1990) and the interaction of superoxide with NO (Wolin *et al.*, 1998; see later). The activity of GSH peroxidase has been demonstrated in vascular tissue to have a major influence on the ability of H_2O_2 to elicit responses mediated by the stimulation of sGC as a result of controlling the amounts of peroxide metabolized by catalase (Mohazzab-H. *et al.*, 1999). Catalase may cooxidize other substances present in tissues (Chance *et al.*, 1979). This could function to inhibit the stimulation of sGC (Burke-Wolin and Wolin, 1990), or the products of these cooxidation reactions might interact with additional signaling processes. However, only minimal information is available on the metabolites present in tissues that are cooxidized by catalase or on signaling systems that could be influenced by products of cooxidation reactions. The redox state of the heme on sGC could be altered by processes related to oxidant stress (Iesaki *et al.*, 1998), and this could be an additional mechanism that influences the sensitivity of this system to activation. Thus, multiple processes are likely to control the expression of the ability of H_2O_2 to influence the activity of sGC as a result of its metabolism by catalase.

SYSTEMS LINKED TO THE METABOLISM OF PEROXIDE BY GSH PEROXIDASE—THIOL REDOX AS A REGULATORY MECHANISM

The generation of GSSG as a result of the metabolism of peroxides by GSH peroxidase seems to be a key pathway for linking H_2O_2 to signaling processes. Normal cellular metabolism is thought to maintain very low GSSG levels. As GSH oxidation begins to occur, it appears that S-thiolation of proteins is a major pathway for the GSSG produced (Brigelius, 1985; Gilbert, 1984; Thomas *et al.*, 1995). If the rate of production of GSSG exceeds its rate of removal and GSSG accumulates, it is likely that the NADP(H) pool will be highly oxidized and that the mechanisms controlling the redox status of thiols on proteins will become impaired. This metabolic condition is likely to promote oxidation of certain protein thiols in the proximity of each other to form protein

disulfides and oxidation of the maintenance thiols that have formed disulfides with GSH in their S-thiolated form. Table I lists some of the proteins known to possess redox-sensitive thiol groups that have the potential to participate in cellular regulatory processes. It appears that a variety of important cellular regulatory systems are potentially regulated by thiol redox processes, including key metabolic enzymes (Brigelius, 1985; Gilbert, 1984), protein kinase C (Gopalakrishna *et al.*, 1999), potassium channels (Bolotina *et al.*, 1994; Duprat *et al.*, 1995; Weir and Archer, 1995), calcium channels (Elliott and Koliwad, 1995; Jones *et al.*, 1983), sGC (Brandwein *et al.*, 1981), and tyrosine phosphatases (Hecht and Zick, 1992). The extent to which GSH redox is altered probably determines which components of cellular regulatory processes are modified and what the resulting consequences of these alterations might be.

SYSTEMS LINKED TO THE METABOLISM OF PEROXIDE BY HEME PEROXIDASES—CYCLOOXYGENASE AND PROSTAGLANDINS

Heme peroxidases could be hypothesized to be ideal sensors of peroxide because these enzymes have the potential to generate signaling molecules by peroxide-dependent cooxidation reactions. Cyclooxygenase is a hemoprotein with heme peroxidase activity which is one of the most sensitive tissue sensors of H_2O_2 formation (Wolin and Mohazzab-H., 1997). The reaction of COX with H_2O_2 appears to place the heme of this enzyme in the oxidation state required for the conversion of arachidonic acid to prostaglandin (PG) G_2 (Wei *et al.*, 1995). Prostaglandin G_2 is a peroxide that as a result of its conversion to PGH_2 replaces the need for H_2O_2 to sustain the COX reaction. Several of the PGH_2 -metabolizing enzymes are hemoproteins, and one of these enzymes,

PGI₂ synthase, appears to be sensitive to inactivation of peroxide-associated oxidant stress (Moncada *et al.*, 1976). Although phagocytic cells have high heme peroxidase activity (e.g., myeloperoxidase), these enzymes appear to be more involved in the production of cytotoxic species such as hypochlorous acid for use in defense mechanisms, and little evidence exists for a role of these systems in signaling processes. Thus, COX appears to be a heme peroxidase that is very sensitive to activation by peroxide, and the profile of prostaglandins that are formed may also be altered by oxidant stress.

Interactions of Other ROS with Signaling Systems

A variety of additional ROS appear to originate from the chemistry and metabolism of superoxide and H₂O₂, and some of these may interact with signaling systems in a manner that promotes physiological responses. The reaction of H₂O₂ with various chelated forms of ferrous (Fe²⁺) iron including heme produces very reactive species, which include hydroxyl radical and oxidized iron species with hydroxyl radical-like chemical reactivity. The formation of hydroxyl radical-like species appears to promote physiological responses (Marshall and Kontos, 1991; Wei *et al.*, 1996). However, the manner through which these species interact with signaling pathways seems to be very poorly understood. The metabolism of peroxide by myeloperoxidase forms hypochlorous acid (HOCl), and HOCl readily reacts with amines (e.g., RNH₂) to form chloramines (RNHCl). Chloramines appear to elicit physiological responses (Tamai *et al.*, 1993); however, the mechanisms involved in the interactions of these species with signaling pathways are generally not known. Certain ROS-associated chemical and enzymatic reactions seem to cause the formation of singlet O₂, a reactive species that has the two unpaired electrons normally present in molecular O₂ ($\cdot\text{O}-\text{O}\cdot$) in a paired molecular structure (O=O). Although the manner through which a species of this type interacts with signaling pathways is essentially not understood, all of the reactive species described in this section have the potential to cause depletion of components of antioxidant systems, which may produce similar forms of oxidant stress and modulation of signaling systems. For example, many of the species discussed in this section have the potential to oxidize cellular GSH and to cause the formation of oxidized lipids, which often have significant biological activity.

Mechanisms Detecting Interactions between NO and ROS by Physiological Signaling Systems

Signaling mechanisms resulting from interactions between NO- and ROS-regulated systems and processes associated with the detection of RNS are discussed in this section. Aspects of the signaling mechanisms of the type

considered here have been the subject of reviews (Wink and Mitchell, 1998; Wolin *et al.*, 1998).

Control of the Production and Levels of RNS

The generation rates of ROS and NO, and the activities of the various antioxidant or metabolizing systems present for ROS and RNS, are likely to function in a manner that markedly controls the amounts of the individual species present and their interactions with signaling processes. The most important interaction appears to be the reaction of NO with superoxide because of its extremely efficient rate constant, and because it involves the primary species produced by NOS and oxidase reactions that produce ROS. The product of this reaction is peroxynitrite, a substance with a half-life of around 1 s. Peroxynitrite has nitrating activity and a hydroxyl radical-like reactivity at physiological pH (Ischiropoulos, 1998; Pryor and Squadrito, 1995; Squadrito and Pryor, 1998). Under physiological conditions, several constituents are present in biological systems at concentrations that significantly compete with the spontaneous decomposition of peroxynitrite. Peroxynitrite reacts with the physiological carbon dioxide–bicarbonate buffering system to produce a nitrating species thought to be nitrosoperoxycarbonate (ONO₂CO₂[−], Squadrito and Pryor, 1998). The formation of this species appears to enhance tyrosine nitration, and it decomposes to generate nitrogen dioxide (NO₂). The major thiol in physiological systems with which ROS and RNS react is GSH. Peroxynitrite appears to directly react with GSH to form *S*-nitroglutathione (GSNO₂), a substance which spontaneously decomposes to NO (Balazy *et al.*, 1998). Under conditions of the reaction of NO with superoxide, the species present may also form *S*-nitrosoglutathione (GSNO). This is likely to occur as a result of the simultaneous presence of NO and nitrogen dioxide, which react to form N₂O₃, a species that directly produces nitrosated thiols (Goldstein and Czapski, 1996). There may be additional substances that have significant rates of reaction with peroxynitrite, or there may be biologically active species that are derived from peroxynitrite. However, the effects of peroxynitrite on signaling mechanisms discussed in this section support the importance of thiol modification and tyrosine nitration as potentially key aspects of the manner through which these species interact with biological systems. Antioxidants are likely to limit the actions of peroxynitrite and its derived RNS. Peroxynitrite appears to readily oxidize thiols (Radi *et al.*, 1991), and cellular GSH may have a major role in preventing many of the additional chemical reactions with cellular constituents that peroxynitrite has been shown (Pryor and Squadrito, 1995) to catalyze. Urate may also be an important physiological scavenger of peroxynitrite (Kooy *et al.*, 1994; Xie and Wolin, 1996) in species that maintain high levels of urate, such as primates and humans (Ames *et al.*, 1981). Peroxynitrite also seems to interact with heme peroxidases (Floris *et al.*, 1993); however, the significance of this process in controlling peroxynitrite levels and signaling is not well understood. Thus, the biological chemistry of

Figure 1 Effects of increases in the levels of superoxide anion (O_2^-) on signaling systems activated by low levels of NO and the consequences of peroxynitrite formation ($ONOO^-$).

the products of the reaction of NO with superoxide may have a major impact of the manner through which RNS interact with cellular signaling systems.

Interactions of ROS with Signaling Systems Regulated by NO

In this section the effects of increasing ROS on some of the better understood signaling systems mediated by NO are considered. Figure 1 contains a model showing some of the important effects superoxide has on NO signaling.

EFFECTS OF ROS ON THE PRODUCTION OF NO

ROS have several interactions that could influence the production of NO. It has been demonstrated that the various forms of SOD in tissues function to minimize the inactivation of NO by superoxide and that Cu,Zn-SOD activity in the endothelium seems to be essential for the release but not the production of NO (Mugge *et al.*, 1991; Omar *et al.*, 1991; Oury *et al.*, 1994). Although the conditions typically used for the assay of NOS activity often promote an interaction of NO with superoxide produced by the NADPH oxidase activity of this enzyme, the levels of SOD in cells that synthesize NO are probably high enough under most circumstances to minimize the effects of superoxide generation by NOS on signaling responses mediated by unmetabolized NO. However, pathophysiological conditions such as exposure of endothelium to elevated levels of low density lipoprotein have been demonstrated to promote detectable levels of NOS-derived superoxide production by these cells, and this is likely to influence NO signaling (Pritchard *et al.*, 1995). It has been demonstrated that a deficiency of the tetrahydrobiopterin cofactor for NOS seems to convert this enzyme in porcine coronary arteries from a source of endothelium-derived NO to a generator of vasoactive levels of H_2O_2 (Cosentino and Katusic, 1995). Whereas cellular antioxidant systems probably prevent ROS from directly influencing the NOS reaction, ROS may influence signaling systems that control the activity of NOS. For example, H_2O_2 has been shown to promote the release of NO from endothelium (Furchgott, 1991), and this appears to be caused by its activating the release of calcium in these cells (Elliott and Koliwad, 1995). ROS have also been shown to influence the expression of NOS activity (Ramasamy *et al.*, 1998). Thus,

ROS can control the production of NO by influencing the signaling mechanisms that control NOS activity and expression. SOD activity appears to be essential for the stabilization of NO by preventing its inactivation by superoxide, and pathophysiological conditions can promote an uncoupling of NADPH consumption from NO production by the NOS reaction. A consequence of uncoupling is probably a lowering in NO production and a shift in signaling controlled by NOS to processes involving ROS and RNS.

EFFECTS OF ROS ON THE STIMULATION OF sGC BY NO

The activation of sGC by NO is markedly influenced by the ROS. As previously mentioned, superoxide reacts with NO, and this attenuates the activation of sGC. Evidence is emerging that this effect of superoxide is an important contributor to many pathophysiological conditions. The effects of NO on the stimulation of sGC by H_2O_2 are discussed later in this chapter. As extracellular concentrations of peroxide approach the millimolar concentration range, H_2O_2 is also an inhibitor of NO-mediated responses associated with the stimulation of sGC (Fayngershteyn *et al.*, 1993). Thus, it appears that this action of peroxide might be associated with a high level of oxidant stress.

EFFECTS OF ROS ON THE INHIBITION OF MITOCHONDRIAL RESPIRATION BY NO

The potent reversible inhibition of respiration by NO is converted to an irreversible effect under conditions where a significant reaction between NO and superoxide is occurring (Xie and Wolin, 1996). Under these conditions, superoxide generation does not markedly alter the potency of NO as an inhibitor of respiration, suggesting that mitochondrial respiration by tissues is likely to be readily inhibited by peroxynitrite formed through the reaction of NO with superoxide. The irreversible inhibition of respiration by peroxynitrite appears to be primarily mediated by damage to iron-sulfur centers of enzymes such as aconitase in the Krebs cycle and complex I and II in the mitochondrial electron transport chain (Hibbs *et al.*, 1990). Studies examining the properties of macrophage cytotoxicity (Hibbs *et al.*, 1990) have detected evidence that availability of Fe^{2+} may help reverse the damage caused to iron-sulfur centers under conditions where peroxynitrite seems to be forming.

POTENTIAL EFFECTS OF ROS ON OTHER NO-MEDIATED SIGNALING PROCESSES

Most of the other actions of NO have not been subjected to studies critically examining the effects of superoxide generation. The interaction of species derived from the reaction of NO with superoxide is considered later in this chapter. It could be hypothesized that responses mediated by unmetabolized NO would be inhibited by a subsequent exposure to increased levels of superoxide. However, responses thought to be mediated by NO that are dependent on the formation of peroxynitrite and not mediated by a subsequent regeneration of NO might be enhanced by increased levels of superoxide.

Interactions of NO with Signaling Systems Regulated by ROS

In this section the effects of increasing NO on some of the better understood signaling systems mediated by ROS are considered. Figure 2 contains a model showing some of the fundamental interactions of NO with ROS signaling mechanisms.

EFFECTS OF NO ON THE PRODUCTION OF ROS

Systems that control the production of ROS are likely to be influenced by NO and its RNS metabolites. The availability of electron donor substrates, the enzymatic activity of some of the oxidases that produce ROS, and the antioxidant systems that metabolize or interconvert ROS are systems that can potentially be influenced by NO and its RNS metabolites. Although it is not possible to consider all of the potential mechanisms that could be involved in these interactions, some of the better documented processes will be mentioned. It is likely that the stimulation of cGMP production by NO will influence cellular activation mechanisms that control ROS production by systems such as the NADPH oxidase of phagocytic cells (Kurose *et al.*, 1995). The manner through which NO inhibits mitochondrial respiration seems to affect the electron transport chain in a fashion that should increase the production of ROS (Poderoso *et al.*, 1998). As mitochondrial function becomes more impaired by RNS, it is likely that this will attenuate the removal of cytosolic NADH by the mitochondrial shuttle systems, potentially resulting in an increase in the production of ROS by the NADH oxidase that utilizes cytosolic NADH (Rabinowitz *et al.*, 1998; Wolin *et al.*, 1996). Elevated levels of RNS are associated with the inhibition of mitochondrial SOD (Ischiropoulos *et al.*, 1992), catalase (Mohazzab-H. *et al.*, 1996), and GSH peroxidase activity (Asahi *et al.*, 1995) and with the oxidation of GSH (Radi *et al.*, 1991). Thus, NO and RNS are likely to influence the production of ROS through multiple processes. At lower levels of NO production, several of its effects are likely to contribute to physiological signaling processes, and some of these processes will be discussed in this section and later in this chapter.

EFFECTS OF NO ON THE STIMULATION OF SGC BY H_2O_2

Exposure of vascular tissue to 50 nM NO for 2 min causes a marked attenuation of subsequent relaxation responses to H_2O_2 that are thought to result from a stimulation of sGC activity by increased peroxide metabolism by catalase (Mohazzab-H. *et al.*, 1996). This inhibitory effect of NO appears to depend on the formation of peroxynitrite (Wolin *et al.*, 1998). However, it is not known if peroxynitrite is inhibiting catalase or if it is producing NO donors that subsequently release over time levels of NO sufficient to inhibit catalase activity. A direct exposure of catalase in buffer to NO under conditions similar to the studies on vascular tissue suggest that the heme of catalase is converted to its compound II form, which is a rather stable, inactive species of catalase. High levels of peroxide are known to reconvert catalase back to its active ferric form (Lardinois, 1995), and

this seems to occur when NO-treated preparations are assayed for catalase activity in the presence of high levels of H_2O_2 (Mohazzab-H. *et al.*, 1996). Thus, NO appears to have a potent inhibitory effect on the stimulation of sGC by H_2O_2 , which seems to result from the formation of peroxynitrite and an attenuation of the function of catalase.

POTENTIAL EFFECTS OF NO ON THE STIMULATION OF PROSTAGLANDIN PRODUCTION BY ROS

Since the metabolism of peroxide by cyclooxygenase appears to be a fundamental component of the initiation and sustainment of the cyclooxygenase reaction, many of the previously considered effects of NO on ROS production and peroxide metabolism could influence the activity of this enzyme in either a stimulatory or inhibitory manner. It appears that peroxynitrite can mimic the effects of the metabolism of peroxide on initiating the cyclooxygenase reaction (Landino *et al.*, 1996). The literature contains multiple observations indicating that NO stimulates and inhibits the production of prostaglandins by tissues. In addition, PGI₂ synthase appears to be readily inhibited by peroxynitrite (Zou and Ullrich, 1996). Thus, NO has multiple potential sites of interaction with the systems that control the production of prostaglandins by tissues, which are currently rather poorly understood.

EFFECTS OF NO ON THE INHIBITION OF MITOCHONDRIAL RESPIRATION BY SUPEROXIDE

Evidence for the inhibition of mitochondrial function by superoxide evolved from studies on the mechanisms of oxygen toxicity. Mitochondrial aconitase, which is inhibited as a result of damage to its iron–sulfur center, is considered to be a cellular site of the pathophysiological actions of superoxide (Gardner *et al.*, 1994). Studies suggest that the presence of NO has the potential to enhance by approximately 10-fold the potency of the irreversible inhibitory actions of superoxide on mitochondrial respiration (Xie and Wolin, 1996). The mechanism involved in this enhancement appears to originate from the formation of peroxynitrite, a species whose actions were discussed previously in this chapter. The significance of this hypothesized potentially important role of NO in the toxicity of oxygen is likely to be better defined by future studies in this field.

Signaling Mechanisms Originating from RNS Derived from ROS

This section focuses on how species derived from interactions between ROS and NO or RNS could be potentially linked to the control of signaling systems. Properties of the interactions between ROS and RNS that seem to be of the most significance in physiological systems were considered previously in this chapter. It appears that peroxynitrite may be one of the most important species involved in the interactions of ROS-derived RNS with signaling systems. Some potential targets for the initiation of signaling mechanisms by peroxynitrite include key thiols, tyrosine, iron–sulfur

Figure 2 Effects of increases in the levels of NO on regulatory systems activated by low levels of ROS and additional signaling interactions that occur as the levels of peroxynitrite (ONOO^-) increase. Potential systems regulated by oxidized GSH (GSSG), protein S-thiolation or thiol oxidation (RSSR), and protein nitrosation (RSNO_x) are listed in Table 1.

centers, and unsaturated fatty acids. Figure 2 contains a model showing how changes in the levels of NO and superoxide are linked to signaling processes as a result of the production of peroxynitrite.

SIGNALING MECHANISMS POTENTIALLY ORIGINATING FROM INTERACTIONS OF RNS WITH THIOLS

Peroxynitrite can modify thiols by reactions that cause nitrosation (RSNO , Goldstein and Czapski 1996), nitration (RSNO_2 , Balazy *et al.*, 1998), and oxidation reactions (Radi *et al.*, 1991), which result in disulfide formation (RSSR'), S-thiolation (RSSG), and thiol oxidation products (RSO_x). Most of these interactions of peroxynitrite with thiols should be given serious consideration as processes that can be involved in signaling because they are usually readily reversible or have the potential to produce tissue storage forms of NO (RSNO_x). It is likely that many of the thiol-containing signaling systems previously considered in this chapter as targets for regulation by ROS-elicited alterations in thiol redox are potential sites of action of peroxynitrite. Table I lists some of the proteins known to possess redox-sensitive thiol groups that have the potential to participate in cellular regulatory processes. Some of the thiol-containing cellular sites that have been demonstrated to be regulated by NO-mediated mechanisms include the key metabolic enzymes glyceraldehyde-3-phosphate dehydrogenase (Mohr *et al.*, 1994) and creatine kinase (Gross *et al.*, 1996), calcium-regulated potassium channels (Bolotina *et al.*, 1994), cyclic nucleotide-gated cation channels (Broillet and Firestein, 1996), Janus kinases (Duhe *et al.*, 1998), tyrosine phosphatases (Caselli *et al.*, 1995), and *N*-methyl-D-aspartate (NMDA) receptors (Lipton *et al.*, 1993).

SIGNALING MECHANISMS POTENTIALLY ORIGINATING FROM INTERACTIONS OF RNS WITH OTHER SYSTEMS

There are additional signaling related processes that are potentially regulated by RNS. It has been suggested that the

nitration of protein tyrosine groups could influence signaling mechanisms regulated by tyrosine phosphorylation (Ischiropoulos, 1998). Modifications of this type could potentially alter the function of a protein in a manner similar to tyrosine phosphorylation, or, if the nitration reaction was a very efficient process on a tyrosine group normally regulated by phosphorylation, it could function as an inhibitor of the phosphorylation-linked signaling. Cells that have significant levels of heme peroxidase activity might also be able to nitrate protein tyrosine groups for regulatory purposes through a more recently documented peroxide-catalyzed metabolism by the peroxidase of the NO decomposition product nitrite (Sampson *et al.*, 1998). However, it is likely that this tyrosine nitration reaction will not be of importance in the majority of cell types present in mammalian organisms *in vivo* because most cells typically contain low heme peroxidase activity. In addition, most of the peroxide needed for this process is likely to be derived from superoxide (which should function to promote peroxynitrite formation), and it is not clear that adequate levels of nitrite are available. Modification of iron-sulfur centers by peroxynitrite is a well-documented process, which was previously discussed in several sections of this chapter related to its role in the control of mitochondrial function and iron metabolism. Peroxynitrite appears to also modify unsaturated fatty acids to form oxidized lipids, with some of the lipids possessing NO_x functional groups (Rubbo *et al.*, 1995). Although these lipids were initially considered for their role in the pathological actions of peroxynitrite, it is possible that certain of the key products of these reactions might be biologically active participants in signaling processes. It is also conceivable that peroxynitrite or other RNS could have interactions with signaling processes through chemical or metabolic reactions in addition to those considered in this chapter.

Signaling Mechanisms of Physiological Processes That Appear to Be Regulated by Systems That Detect RNS and ROS

In this section some of the better documented roles for the ROS and RNS signaling mechanisms discussed in this chapter in physiological and pathophysiological regulatory processes are highlighted. Several of the systems mentioned, but not discussed in detail, are considered in greater depth in other chapters of this book.

The Importance of the Regulation of sGC by ROS and RNS

There appear to be multiple mechanisms through which ROS and RNS can alter the activity of sGC. The most potent interactions with sGC include the stimulation of sGC by NO and H_2O_2 metabolism by catalase. Although the stimulation of sGC by NO has been studied in multiple systems, evidence for the regulation of sGC through peroxide metabolism by catalase has only been described in a few vascular

preparations. Multiple redox systems, including GSH peroxidase, NO, superoxide, and the presence of electron donors for catalase, may function in tissues normally to inhibit expression of the stimulation of sGC by the catalase-dependent mechanism. Because the production of H_2O_2 is typically regulated by oxygen tension, tissue redox, and certain receptor regulated oxidases, the control of sGC activity by the catalase mechanism is likely to have a role in responses involved in the sensing of changes in oxygen tension, lactate produced by tissue hypoxia, and receptor-regulated oxidant signaling. The peroxide-dependent regulation of sGC appears to participate in responses of pulmonary arteries to hypoxia (Burke-Wolin and Wolin, 1990; Wolin *et al.*, 1996), of coronary arteries to posthypoxic reoxygenation (Mohazzab-H. *et al.*, 1999), and of the relaxation of multiple vascular preparations to levels of lactate that are produced during exercise (Wolin *et al.*, 1999b).

Attenuation of the regulation of sGC by an inactivation of NO by superoxide appears to be one of the most potent biological actions of superoxide that is observed in physiological systems. The activities of the various forms of SOD present in tissues seem to have a major role in controlling the expression of this interaction. Because it appears that a NO-regulated form of sGC is present in a large number of cell types, processes including the attenuation of NO stimulation of sGC by superoxide and perhaps the formation of NO donors in tissues as a result of the production of significant levels of peroxynitrite at elevated levels of NO should be considered as fundamental cellular signaling processes. It is already well documented that the attenuation of NO-mediated stimulation of sGC by superoxide can antagonize the actions of NO that are involved in promoting smooth muscle relaxation, the inhibition of platelet aggregation, the inhibition of neutrophil adhesion, and neurotransmission in a variety of experimental systems.

The Importance of the Regulation of Arachidonic Acid Metabolism by ROS and RNS

The potent effects of peroxide on stimulating prostaglandin formation by cyclooxygenase appears to be a basic component of certain physiological regulatory processes. Thus, the role of additional effects of NO, RNS, and ROS on arachidonic acid metabolism in biological processes remains to be better defined. For example, certain oxygen-elicited vascular responses, such as the acute increase in blood flow (reactive hyperemia) following a brief arterial occlusion (Wolin *et al.*, 1990) and the promotion of the production of prostaglandin formation by inflammatory processes, appear to be mediated in part by the production of H_2O_2 (Gurtner and Burke-Wolin, 1991). Although it is well documented that the activity of prostacyclin or PGI_2 synthase is inhibited by peroxynitrite and elevated levels of peroxide (Moncada *et al.*, 1976; Zou and Ullrich, 1996), and that several diseases associated with oxidant stress alter the production of prostaglandins (Gurtner and Burke-Wolin, 1991), the role of ROS and RNS in these changes remains to be better defined.

The Importance of the Regulation of Aspects of Tissue Metabolism and Respiration by ROS and RNS

NO controls tissue oxygen consumption in conscious dogs in a manner that appears to be independent of hemodynamic changes and increases in respiration promoted by exercise and cardiac pacing (Shen *et al.*, 1994, 1995; Bernstein *et al.*, 1996). It is also well documented that conditions associated with increased oxidant stress, such as hyperoxia (Gardner *et al.*, 1994) and tissue ischemia/reperfusion (Granger, 1988), and increased peroxynitrite production during macrophage cell killing (Hibbs *et al.*, 1990) are associated with irreversible effects mitochondrial function. NO appears to regulate respiration in a manner that improves the efficiency of tissue oxygen utilization (Bernstein *et al.*, 1996; Wolin *et al.*, 1999a), whereas the formation of peroxynitrite seems to cause a loss of efficiency of oxygen utilization (Schulz *et al.*, 1997). Thus, NO, superoxide, peroxynitrite, and other species are likely to have important roles in controlling mitochondrial function under physiological and pathophysiological conditions. The function of certain other thiol-containing metabolic enzymes, including glyceraldehyde-3-phosphate dehydrogenase (Mohr *et al.*, 1994) and creatine kinase (Gross *et al.*, 1996), also appears to be readily inactivated by tissue injury processes associated with oxidant stress and/or the formation of RNS. Many of the consequences of these metabolic effects of NO, peroxynitrite, and ROS on these systems remain to be elucidated.

The Importance of the Regulation of Thiol Redox Processes by ROS and RNS

Multiple interactions of ROS and RNS with systems that are influenced by thiol redox have been discussed throughout this chapter. These interactions include modification of thiols by several different forms of oxidation including S-thiolation, nitrosation, and nitration. It is likely that many different forms of signaling are mediated by the various ways thiols can be modified, and each pathway will have subtle ways through which thiol redox processes control the systems being regulated. The susceptibility of each of the thiol groups on proteins to modification is influenced by the reactivity and accessibility to the process it is being modified by. Thus, aspects of the processes that control thiol redox may permit a diversity of systems to be regulated by the behavior of individual thiol groups that are components of signaling mechanisms for each regulatory system. Many key components of cellular regulatory systems have thiol groups whose redox status appears to influence the function of the system. Table I lists some of the enzymes influenced by thiol redox that are potential contributors to cellular control mechanisms. Thus, thiol redox processes can participate in the signaling mechanisms that control metabolism (Gilbert, 1984; Brigelius, 1985; Mohr *et al.*, 1994; Gross *et al.*, 1996; Ji *et al.*, 1999), potassium channels (Bolotina *et al.*, 1994; Weir and Archer, 1995), calcium channels (Elliott and Koliwad, 1995; Jones *et al.*, 1983), cyclic nucleotide-gated

cation channels (Broillet and Firestein, 1996), protein kinase C (Gopalakrishna *et al.*, 1999), sGC (Brandwein *et al.*, 1981), tyrosine phosphatases (Hecht and Zick, 1992; Caselli *et al.*, 1995), and NMDA receptor function (Lipton *et al.*, 1993). These mechanisms are likely to be involved in the control of important physiological responses, and many of the signaling systems are activated by ROS and RNS through mechanisms that are not well understood. Some of these mechanisms and physiological processes are mentioned next.

Other Physiological Regulatory Systems that Appear to Be Controlled by ROS and RNS

The nature of many of the processes discussed in this chapter suggests they have important fundamental roles in signaling mechanisms involving ROS and RNS. Multiple additional actions of ROS and RNS on signaling systems involved in physiological responses have been observed, but the actual manner through which the ROS or RNS interact with the signaling system have often not been identified. Some examples include the activation of several phospholipases, protein kinase C, extracellular signal regulated kinases, and mitogen-activated protein kinases and the regulation of multiple signaling and gene expression processes through redox-sensitive transcription factors including nuclear factor κ B (NF- κ B) and activator protein-1 (AP-1) (Lander, 1997; Suzuki *et al.*, 1997; Abe and Berk, 1998). These processes have important roles in the control of smooth muscle contractile behavior, in the function of antioxidant systems, in the expression of adhesion proteins, and in cell proliferation, apoptosis, and many other basic physiological processes.

Concluding Remarks

Evidence is accumulating that ROS and RNS interact with cellular control mechanisms in a manner that is consistent with the many of the processes being components of fundamental signaling mechanisms. Most of the individual ROS and RNS have unique ways of interacting with or being sensed by signaling systems. There appear to be second messenger-like regulatory processes that are controlled by rapid changes in the levels of specific ROS and perhaps RNS that are formed during normal physiological responses such as the sensing of oxygen tension and stimulation of receptors. Slightly higher levels or a more prolonged exposure to increased lower levels of ROS and RNS appear to participate in the control of additional regulatory processes important to physiological or pathophysiological function such as controlling the expression of adhesion proteins, the activation of cellular proliferation, and the expression of multiple genes. Levels of ROS and RNS that strongly perturb antioxidant defense systems also seem to activate signaling responses. However, it appears that these mechanisms may be more

involved in pathophysiological processes, including responses of tissues to injury, such as apoptosis, and in the activation of mechanisms of repair. Thus, ROS and RNS appear to participate in a diversity of important signaling mechanisms, and much remains to be learned regarding how these systems are designed to function.

Acknowledgments

I thank collaborators and members of my laboratory quoted in the references for their contributions to developing an understanding of signaling processes. Studies from my laboratory have been funded by grants from the American Lung Association, the American Heart Association, and the National Institutes of Health (HL31069 and HL43023).

THE BIOLOGY OF IRON IS INTIMATELY CONNECTED WITH NITRIC OXIDE (NO) AND OXYGEN RADICALS. HERE WE ILLUSTRATE HOW NO AND OXYGEN METABOLITES BIOCHEMICALLY INTERACT WITH IRON AND, IN ADDITION, HOW THESE REACTIVE MOLECULES FUNCTION AS SIGNALS TO REGULATE CELLULAR IRON METABOLISM. WE FIRST PROVIDE AN OVERVIEW OF THE IMPORTANCE OF IRON IN BIOLOGY AND DESCRIBE THE DIFFERENT STRATEGIES THAT CELLS AND ORGANISMS, FROM BACTERIA TO HUMANS, HAVE ADAPTED TO ACQUIRE NUTRITIONAL IRON. EMPHASIS IS GIVEN TO THE POSTTRANSCRIPTIONAL REGULATORY CIRCUIT THAT CONTROLS CELLULAR IRON METABOLISM IN HIGHER EUKARYOTES: THE EXPRESSION OF PROTEINS WITH KEY FUNCTIONS IN IRON UPTAKE, STORAGE, AND UTILIZATION IS COORDINATELY REGULATED AT THE LEVELS OF mRNA TRANSLATION AND STABILITY. THE MECHANISM INVOLVES BINDING OF TWO HOMOLOGOUS CYTOPLASMIC IRON REGULATORY PROTEINS, IRP1 AND IRP2, TO IRON RESPONSIVE ELEMENTS (IREs), CONSERVED STEM-LOOP STRUCTURES IN THE UNTRANSLATED REGIONS OF mRNAs. IRON REGULATORY PROTEINS RESPOND TO IRON BUT ALSO TO IRON-INDEPENDENT SIGNALS, INCLUDING NO AND OXIDATIVE STRESS. MECHANISTIC AND PHYSIOLOGICAL ASPECTS OF THE REGULATION OF IRON METABOLISM BY NO AND OXIDATIVE STRESS ARE DISCUSSED AT THE END OF THE CHAPTER.

The Biology of Iron: Role of Oxygen Radicals and NO

Iron is the second most abundant transition metal on the earth's crust after aluminum. In chemical terms, iron is characterized by its capacity to form a variety of coordination complexes with organic molecules and by its electrochemical redox potential between the two basal ferrous Fe(II) and ferric Fe(III) states. These features form the basis of a provocative evolutionary hypothesis: iron minerals on the earth's crust may have provided a substrate for crucial redox reactions to generate elementary energy sources for primitive forms of life (Wächtershäuser, 1992). Contemporary living cells have exploited the advantageous chemical properties of iron and have utilized iron in macromolecules to fulfill a wide range of fundamental structural and metabolic

functions. These include oxygen transport and a plethora of electron transfer and catalytic reactions (Aisen, 1994).

The broad spectrum of iron-dependent biochemical activities implies a dynamic and flexible mode for iron coordination within proteins. Iron-binding proteins can be classified into two major groups, namely, those containing heme or nonheme iron (Frausto da Silva and Williams, 1991). Heme, a very common prosthetic group, is composed of protoporphyrin IX and Fe(II), which can be oxidized to Fe(III) to form hemin. Only Fe(II) can be utilized for enzymatic heme biosynthesis. The insertion of the ferrous iron ion into the tetrapyrrole ring of protoporphyrin IX is catalyzed by ferrochelatase, and this represents the terminal step of the heme biosynthetic pathway. Heme serves as the oxygen carrier in hemoglobin and myoglobin, and it participates in electron

transfer reactions in cytochromes. Heme also constitutes part of the active site of many enzymes, including nitric oxide synthetases and catalase.

The most prevalent forms of nonheme iron in proteins are the iron–sulfur clusters (Frausto da Silva and Williams, 1991; Beinert *et al.*, 1997). Different types of iron–sulfur clusters have been identified, including 2Fe–2S, 3Fe–4S, and 4Fe–4S. Iron–sulfur clusters play diverse functional roles in electron transfer reactions (Rieske proteins and ferredoxins), transcriptional regulation (bacterial transcription factors SoxR and FNR), structure stabilization (bacterial endonuclease III), and catalysis (dehydratases, including aconitase). Some bacterial enzymes contain more complex iron–sulfur centers together with an additional metal, such as Fe–Mo–S clusters in nitrogenase (to catalyze nitrogen fixation), or Ni–Fe–S clusters in hydrogenase (to catalyze the generation of molecular hydrogen). Mammalian oxidases, such as cyclooxygenase and lipoxygenase, contain a mononuclear iron center instead of heme or iron–sulfur iron. In these enzymes, iron is involved in the activation of the substrate (e.g., arachidonic acid) to be oxidized. The remarkable variety of ways by which iron can coordinate to metalloproteins is also reflected in the unusual diiron–oxo bridge Fe–O–Fe of ribonucleotide reductase, which catalyzes the reduction of ribo- to deoxyribonucleotides, a critical step in DNA synthesis.

Considering the importance of iron as a metal cofactor, one would predict that prokaryotic as well as eukaryotic cells require sufficient supplies of iron for growth, and that iron deficiency in higher organisms, particularly in humans, is associated with various disorders (Andrews, 1999). The vast majority (70%) of iron in the adult human body is utilized in erythroid cells for the synthesis of hemoglobin (Ponka, 1997). The depletion of body iron stores thus results in impaired erythropoiesis, leading to anemia. In light of the constraints and relative inefficiency of dietary iron absorption (see below), it is not surprising that iron deficiency anemia constitutes one of the most common nutritional pathological conditions, affecting ~20% of the world's population (DeMaeyer and Adiels-Tegman, 1985).

Too little iron is bad, but too much iron is even worse. This is evident from the severe disorders of primary and secondary iron overload (Andrews, 1999). Hereditary hemochromatosis is a highly frequent autosomal recessive disease which affects 1:400 individuals in Western populations (Andrews and Levy, 1998; Cox and Kelly, 1998). The defect in hereditary hemochromatosis causes an increase in iron absorption that ultimately leads to iron deposition in tissue parenchymal cells. Repeated blood transfusion, as may be required in the treatment of various anemias, leads to secondary iron overload, mainly in the reticuloendothelial system (Pippard, 1994). Another interesting example of a disorder associated with disturbed iron homeostasis is Friedreich's ataxia, an autosomal recessive disease where iron accumulates in the mitochondria, particularly of the heart and the nervous system (Koenig and Mandel, 1997). In general, excess iron can lead to tissue degeneration and the develop-

ment of cirrhosis, hepatoma, or heart failure. Interestingly, epidemiological studies suggest that even in healthy individuals, increased body iron stores constitute a risk factor for ischemic heart disease and cancer (Stevens *et al.*, 1988).

The toxicity of iron is based on Fenton/Haber–Weiss chemistry; the iron (or copper)-catalyzed generation of hydroxyl radical (OH·) by derivatives of dioxygen, such as superoxide (O₂^{·-}) and hydrogen peroxide (H₂O₂) (Fig. 1). Iron (and copper) also contribute to the generation of organic reactive species, such as peroxy (ROO·), alkoxy (RO·), thiyl (RS·), and thiyl–peroxy (RSOO·) radicals (Fig. 1). Oxygen and organic free radicals are highly aggressive compounds that attack virtually all cellular macromolecules. The result is damage to membranes, proteins, and nucleic acids, which can ultimately lead to cell death or tissue degeneration (Halliwell and Gutteridge, 1990). Cells produce spontaneously “reactive oxygen intermediates” (ROIs) by incomplete reduction of dioxygen during aerobic respiration in mitochondria. The superoxide dismutases, catalase, and glutathione peroxidase metabolize superoxide and hydrogen peroxide, and they serve as guardians to protect cells from oxygen-dependent iron toxicity (Cadenas, 1989; Sies, 1997). An increase in levels of ROIs, referred to as oxidative stress, is a hallmark of numerous pathological conditions (Ferrari *et al.*, 1998; Beal, 1998; Sun and Chen, 1998), including inflammation, ischemia–reperfusion injury, and neurodegenerative disorders, such as amyotrophic lateral sclerosis, Alzheimer's, and Parkinson's disease. Oxidative stress has also received attention in the context of aging (Ames *et al.*, 1993; Shigenaga *et al.*, 1994) and cancer (Dreosti, 1998; Poulsen *et al.*, 1998). Thus, it is not surprising that oxidative stress leads to activation of complex genetic defence mechanisms (Baeuerle *et al.*, 1996; Kyriakis and Avruch, 1996).

Apart from being toxic by-products, oxygen radicals are utilized by specialized cells of the immune system to combat bacterial infection (Baggiolini and Thelan, 1991; Hampton

et al., 1998). For this purpose, macrophages and neutrophils are stimulated during the “oxidative burst” to release high levels of superoxide, generated enzymatically by a plasma membrane-bound NADPH oxidase, that immediately undergoes dismutation to hydrogen peroxide. The effectiveness of this immune response very likely depends on the presence of iron and the recycling of oxygen radicals by Fenton/Haber–Weiss chemistry. In addition, the bactericidal (and cytotoxic) capacity of the oxidative burst is enhanced by nitric oxide (NO) and other reactive oxygen species such as peroxynitrite (ONOO[−]) and hypochlorite (OCl[−]). The inducible nitric oxide synthase (iNOS or NOS2) in macrophages produces NO to inactivate crucial iron-containing proteins in bacteria (or target cells), including aconitase, complexes I and II of the respiratory chain, and ribonucleotide reductase. Peroxynitrite and hypochlorite are potent oxidants; the former is generated spontaneously by superoxide and nitric oxide, whereas the latter is synthesized by the heme-containing enzyme myeloperoxidase from hydrogen peroxide and chloride.

On a chemical basis, it becomes evident that iron, oxygen radicals, and NO are partners that possess an enormous toxic potential. Therefore, their concentrations should be tightly controlled. Oxygen radicals and NO are short-lived intermediates, and their activities are antagonized by degrading enzymes or low-molecular-weight antioxidants. On the other hand, higher organisms have a limited capacity to remove or eliminate iron. Iron stores are instead controlled at the level of absorption, which is, under normal conditions, very limited. Thus, the regulation of iron homeostasis poses a challenge to satisfy the metabolic needs of cells and organisms for iron and at the same time to minimize the risk of iron toxicity in an aerobic environment.

Iron Metabolism

The major problem of iron assimilation by living cells is its limited bioavailability. Soluble Fe(II) is readily oxidized in aqueous solutions to the essentially insoluble (at neutral pH) ferric hydroxide. Many bacteria cope with this problem by synthesizing and secreting ferric iron chelators, the siderophores (Wooldridge and Williams, 1993; Braun, 1997). Similarly, some plants secrete phytosiderophores. These soluble, low-molecular-weight carriers transport iron across cell membranes by binding to specific receptors. In the reducing intracellular milieu, Fe(III) is liberated and converted to Fe(II).

The budding yeast *Saccharomyces cerevisiae* utilizes an elegant mechanism to acquire environmental iron (Klausner and Dancis, 1994; Askwith *et al.*, 1996; Kaplan and O’Halloran, 1996; Dancis, 1998; Radisky and Kaplan, 1999). The first step involves reduction of ferric to ferrous iron in the vicinity of the cell. Subsequently, Fe(II) is either directly internalized by a low-affinity transporter ($K_m = 40 \mu M$), or reoxidized to Fe(III) and internalized by a distinct high-affinity transporter ($K_m = 0.15 \mu M$). The identification,

molecular cloning, and functional characterization of components of these pathways provided valuable insights into the underlying molecular mechanisms. The first step of Fe(III) reduction is catalyzed by two plasma membrane-bound ferric (and cupric) reductases, encoded by FRE1 (Dancis *et al.*, 1992) and FRE2 (Georgatsou and Alexandraki, 1994). A good candidate for the low-affinity ferrous transporter is encoded by FET4 (Dix *et al.*, 1994), which has six potential transmembrane domains. The high-affinity transporting system comprises two activities: (1) a plasma membrane-bound multicopper ferroxidase, encoded by FET3 (Askwith *et al.*, 1994), that is homologous to mammalian ceruloplasmin, a soluble ferroxidase in the plasma, and (2) a permease, apparently encoded by FTR1 (Stearman *et al.*, 1996). Fet3p, with a single transmembrane domain, associates with Ftr1p, which potentially spans the plasma membrane at six sites. It appears that oxidation of Fe(II) by Fet3p drives Fe(III) to Ftr1p for internalization. The assembly of Ftr1p–Fet3p complexes is required for cell surface expression and for iron transport. Interestingly, related mechanisms appear to operate in some plants. However, these are far less well defined. A gene from *Arabidopsis thaliana*, IRT1, encoding a putative membrane-bound Fe(II) transporter protein has been cloned (Eide *et al.*, 1996) and awaits further functional characterization.

Thus, unicellular organisms and plants have adopted two strategies to assimilate environmental iron for their nutritional needs. These involve either (a) capture of soluble Fe(III) chelates from the extracellular milieu with siderophores, with the iron-loaded siderophores, or even host iron-binding proteins, then being transported by binding to specific cell surface receptors, or (b) reduction of Fe(III) to Fe(II) catalyzed by the extracellular domain of membrane-spanning ferric reductases, and internalization via low- or high-affinity iron transporters.

These principles have been conserved in higher organisms. In mammals, dietary iron is absorbed in the upper part of the small intestine (mainly in the duodenum) (Skikne and Baynes, 1994). Iron is then transported through the mucosal cells to the portal circulation and, finally, delivered to tissues and the erythroid bone marrow. Duodenal iron absorption involves solubilization of Fe(III) in the acidic pH of the intestinal lumen, reduction to Fe(II) (Raja *et al.*, 1992; Riedel *et al.*, 1995) by still ill-characterized reductase(s) and ascorbate, and internalization by a ferrous transporter. In the bloodstream, iron is scavenged by transferrin, a protein that functions like a siderophore and delivers iron to the cells by binding to a specific cell surface receptor (see below). Interestingly, the distinct strategies for intestinal iron absorption and cellular iron uptake are strongly reminiscent of the modes of iron assimilation by yeast and bacteria, respectively.

Early studies employing radiolabeled iron have identified the duodenum as the major site for dietary iron absorption (Skikne and Baynes, 1994). Iron from the intestinal lumen is taken up across the brush border of mature enterocytes. These specialized cells are localized at the microvillar tips

of the duodenal epithelium and derive from precursor mucosal cells in the crypts. The maturation process is associated with migration of the enterocytes from the crypts to the villi. Newly absorbed iron is transported across the basolateral membrane into the circulation and binds to transferrin (Fig. 2). The mature enterocytes are the critical cells for the regulation of dietary iron absorption. In hereditary hemochromatosis the enterocytes absorb pathologically high levels of iron. At the other end of the spectrum, the causative defect in some forms of microcytic anemia lies in the failure of enterocytes to transfer sufficient quantities of iron to the plasma.

Despite the well-established role of enterocytes in the regulation of iron absorption, relatively little progress has been made toward identifying the molecules involved in these processes. However, the more recent identification of genes involved in iron acquisition and its control have greatly stimulated the field. One of these genes encodes a divalent metal transporter, DMT1, first reported in the literature as Nramp2 or DCT1 (Fleming *et al.*, 1997; Gunshin *et al.*, 1997). Genetic studies have implicated DCT1/Nramp2, a member of the Nramp (natural resistance-associated macrophage protein) family of proteins, as a candidate for an intestinal ferrous iron transporter. In microcytic anemia (*mk*) mice, the G185R mutation affects a predicted transmembrane domain of the DCT1/Nramp2 protein. This mutation appears to be responsible for diminished iron absorption that renders the animals anemic due to severe iron deficiency (Fleming *et al.*, 1997). Furthermore, mammalian cells transfected with a DCT1/Nramp2 cDNA (Su *et al.*, 1998), or *Xenopus* oocytes microinjected with mRNA fractions enriched in DCT1/Nramp2 mRNA (Gunshin *et al.*, 1997), display enhanced iron uptake. In addition to Fe(II), DCT1/Nramp2 is also capable of transporting a variety of divalent cations, including Cu(II), Zn(II), Cd(II), Mn(II), and Co(II) (Gunshin *et al.*, 1997).

The pathway of iron transfer across the basolateral membrane of enterocytes is incompletely understood. Genetic approaches may prove to be informative, as a relevant

animal model is already available, namely, the sex-linked anemia (*sla*) mouse. Hemizygous male *sla* mice suffer from microcytic anemia. However, in contrast to the *mk* mice that have impaired capacity for iron absorption, the *sla* mice have a defect in iron delivery to the circulation. The gene defective in the *sla* mouse, *Heph*, has been cloned (Vulpe *et al.*, 1999). It encodes hephaestin, a transmembrane-bound protein, that shares homology with ceruloplasmin. The recent identification and cloning of a strong candidate for the long-sought basolateral iron transporter, named IREG1 (McKie *et al.*, 2000) or ferroportin 1 (Donovan *et al.*, 2000) is expected to provide new insights into the mechanisms of iron transport.

Serum transferrin (Tf), a monomeric glycoprotein of 80 kDa, is the carrier of iron in the blood and binds two Fe(III) ions with high affinity ($K_d = 10^{-23}$ M at neutral pH) (Ponka *et al.*, 1998). Only ~30% of Tf is saturated with iron under physiological conditions. Tf possesses intrinsic ferroxidase activity and belongs to a family of related proteins found in other biological fluids, such as lactoferrin in milk and ovotransferrin in egg white. Delivery of iron to Tf may involve the ferroxidase activity of ceruloplasmin. In contrast to yeast Fet3p and to intestinal hephaestin, which are both transmembrane proteins, ceruloplasmin is soluble. Its precise biological function is still unclear, but it has always been considered as a factor involved in iron egress from tissues (de Silva *et al.*, 1996). This is also strongly supported by the phenotype of aceruloplasminemic patients, who suffer from impaired ceruloplasmin synthesis and develop tissue iron overload (Harris *et al.*, 1995; Gitlin, 1998). Studies have also implicated ceruloplasmin in hepatocyte iron uptake (Mukhopadhyay *et al.*, 1998), but the physiological significance of this finding is not clear yet. The identification of potential ceruloplasmin-interacting proteins, by analogy to the yeast example, may shed more light on these questions.

The major route for iron uptake into erythroid and non-erythroid cells utilizes the binding of diferric Tf to the cell surface transferrin receptor (TfR) (Fig. 3). TfR is a homo-

Figure 2 Dietary iron absorption in the duodenum. Ferrous iron is transported from the intestinal lumen across the brush border of mature enterocytes. The apical transport very likely involves the divalent metal transporter DCT1/Nramp2. Following transport across the basolateral membrane of the mature enterocyte, iron is delivered to the circulation and binds to apotransferrin (apo-Tf) to form diferric Tf. The iron status of the precursor cells in the crypts appears to reflect the iron absorption capacity of mature enterocytes.

Figure 3 The Tf-TfR cycle in mammalian cells. Extracellular diferric Tf binds to cell surface TfR, and the Tf-TfR complex is internalized by endocytosis. Iron is released, following acidification of the endosome, by a pathway that may involve the activity of the divalent metal transporter DCT1/Nramp2. In the cytoplasm, iron is utilized for the synthesis of iron-containing proteins, and excess is stored in ferritin. ApoTf-TfR complex dissociates at the cell surface. Association of TfR with HFE may prevent binding of extracellular diferric Tf to TfR.

dimeric glycoprotein of 180 kDa that can bind two molecules of Tf. At neutral pH, diferric Tf has a ~500-fold higher binding affinity to the TfR than apoTf (Ponka *et al.*, 1998). The internalization of TfR occurs by classic receptor-mediated endocytosis. In the acidic milieu of the endosome (pH ~5.5) the affinity of ferric iron to TfR-bound Tf drops dramatically, resulting in its release. The apoTf-TfR complex recycles on the cell surface, while ferric iron is reduced to ferrous and delivered from the endosome into the cytosol for utilization by an as yet poorly defined mechanism. A fraction of released iron remains bound to low-molecular-weight chelates, presumably including citrate, ATP, pyrophosphates, or ascorbic acid, and determines the iron status of the cell. This “regulatory iron pool” can be monitored by fluorescence techniques (Epsztejn *et al.*, 1997). Not much is known about iron metabolism in intracellular organelles. Genetic and biochemical data suggest that frataxin, a newly characterized gene which is mutated in patients with Friedreich’s ataxia (Koenig and Mandel, 1997), has an important role for the maintenance of iron homeostasis in the mitochondria by encoding a protein that stimulates iron efflux (Babcock *et al.*, 1997; Radisky *et al.*, 1999).

Excess iron is sequestered in ferritin, the main intracellular iron storage protein, which is composed of 24 subunits of H- and L-chains (21- and 19-kDa, respectively) (Aisen and

Listowski, 1980; Theil, 1987; Ponka *et al.*, 1998). These assemble to a symmetric shell-like structure with a potential to store up to 4500 ferric iron ions. Functional ferritin molecules are composed of different proportions of L- and H-subunits in different tissues. For example, L-subunits predominate in liver and H-subunits in heart “isoferritins.” Iron incorporation into ferritin requires a ferroxidase activity associated with H-subunits and a nucleation center associated with L-subunits. Iron mobilization from ferritin, to cover cellular metabolic needs, is incompletely understood and may involve structural changes in ferritin subunits (Takagi *et al.*, 1998). It is also conceivable that utilization of ferritin-bound iron may be coupled with ferritin turnover (Radisky and Kaplan, 1998). Overall, ferritin constitutes a versatile device to sequester and detoxify considerable quantities of iron and, moreover, maintains iron in a soluble, bioavailable form.

The mechanism of intracellular iron transport from the endosome into the cytoplasm is not clear. Genetic data arising from the *mk* mouse and Belgrade (*b*) rat models have implicated DCT1/Nramp2 in this process. DCT1/Nramp2 in the *b* rat carries the same G185R mutation, as in the *mk* mouse, and displays a similar phenotype: a severe iron deficiency anemia (Fleming *et al.*, 1998). Previous reports had suggested that the defect in the *b* rat lies in the failure to deliver transferrin-bound iron into the cytoplasm (Garrick *et*

al., 1993). Taken together, the experimental data obtained with the *mk* mouse and the *b* rat imply that the function of DCT1/Nramp2 may extend from dietary iron absorption in enterocytes to intracellular iron transport across the endosomal membrane in different cell types. Clearly, these attractive speculations await more direct experimental support. The identification of DCT1/Nramp2 is more recent and its characterization thus still preliminary.

Although understanding the function of DCT1/Nramp2 is definitely challenging, the product of another recently identified gene poses no less of a puzzle: HFE is an atypical MHC class I molecule that carries mutations in the vast majority of hereditary hemochromatosis patients (Feder *et al.*, 1996). The most prevalent (>80%) of these is a single C282Y point mutation that abrogates the physical interaction of HFE with β 2-microglobulin and thus prevents HFE processing in the Golgi apparatus and HFE expression on the cell surface. Unlike typical MHC class I molecules, HFE does not present peptide antigens (Lebrón *et al.*, 1998). Genetic and clinical evidence suggests that HFE negatively regulates iron absorption in the intestine and, possibly, iron release from macrophages. An unequivocal function of HFE in the control of iron metabolism has been established by the targeted disruption of the HFE gene in mouse: HFE knockout mice develop iron overload in tissue parenchymal cells (Beutler, 1998; Zhou *et al.*, 1998). Interestingly, the same phenotype was earlier observed in β 2-microglobulin knockout mice (de Sousa *et al.*, 1994; Rothenberg and Volland, 1996), suggesting that processing of HFE is critical for its function. However, the mechanism for the exact role of HFE in iron metabolism remains as yet elusive. The finding that HFE has the potential to interact with the TfR and decrease the affinity of Tf for the TfR (Parkkila *et al.*, 1997; Gross *et al.*, 1998; Lebrón *et al.*, 1998) has raised the possibility that HFE may have an inhibitory effect on iron uptake by TfR. On the other hand, iron uptake studies in crypt and villar enterocytes, together with the intracellular localization of HFE in crypt cells, have led to an alternative hypothesis (Waheed *et al.*, 1999). According to this, HFE may positively regulate iron delivery from plasma to immature crypt enterocytes by the Tf-TfR route. The iron status of these precursor cells appears to reflect the capacity of mature enterocytes for dietary iron absorption. A signaling function of HFE may be critical for programming differentiating mucosal cells to reduced dietary iron absorption on maturation. This hypothesis is supported by the finding that HFE knockout mice express inappropriately high levels of DCT1/Nramp2 mRNA (Fleming *et al.*, 1999). Moreover, DCT1/Nramp2 mRNA levels are increased in duodenal biopsy samples of hemochromatosis patients carrying the C282Y mutation in HFE (Zoller *et al.*, 1999).

The functional characterization of DCT1/Nramp2 and HFE has generated new questions about the role of these proteins in iron metabolism. The assessment of the biological implications associated with the function of DCT1/Nramp2 and HFE has created immense excitement. However, at this point functional hypotheses have to be viewed as such and require further experimental evaluation.

Posttranscriptional Regulation of Iron Metabolism

The expression of many genes involved in mammalian iron metabolism is controlled at the posttranscriptional level in response to iron concentration (Klausner *et al.*, 1993; Kühn, 1994; Hentze and Kühn, 1996; Rouault *et al.*, 1996; Richardson and Ponka, 1997; Pantopoulos and Hentze, 1999). Thus, in iron-starved mammalian cells, which do not need to store but rather take up iron, ferritin mRNA translation is inhibited, and the otherwise unstable TfR mRNA is stabilized. However, in iron-loaded cells, which have to store excess iron and reduce additional uptake, ferritin mRNA is readily translated, and TfR mRNA is prone to degradation. The common denominator in these homeostatic responses is the presence of so-called iron responsive elements (IREs) in the untranslated regions (UTRs) of these mRNAs. The IRE is a phylogenetically conserved hairpin structure (Theil, 1994), originally identified in the 5' UTR of the mRNAs encoding ferritin H- and L-chains (Hentze *et al.*, 1987). Soon thereafter, multiple IREs were found in the 3' UTR of TfR mRNAs (Müllner and Kühn, 1988; Casey *et al.*, 1989). Typical IREs consist of about 30 nucleotides that form a structured loop with the sequence 5'-CAGUGN-3' and a stem with moderate stability ($\Delta G \approx -7$ kcal/mol), interrupted by a bulge that contains an unpaired 5' C residue (Fig. 4).

The IRE constitutes a binding site for either of two iron regulatory proteins, IRP1 and IRP2, which are activated for

Figure 4 The IRE consensus motif consists of a hexanucleotide loop (5'-CAGUGN-3') and a stem, interrupted by a bulge with an unpaired C residue. Base pairing between C¹ and G⁵ is functionally important. N⁶ could be any nucleotide but not G, which would potentially disrupt C¹-G⁵ interaction by C¹-G⁶ pairing. The bulge may consist of an asymmetric tetranucleotide, as in many ferritin mRNAs (left), or of a single C residue (right).

high-affinity IRE binding by iron starvation. The IRE–IRP binding results in specific translational arrest of ferritin mRNAs (Rouault *et al.*, 1988) and stabilization of TfR mRNA (Koeller *et al.*, 1989). Conversely, in iron-replete

cells, IRE binding activity decreases dramatically, permitting ferritin H- and L-chain mRNA translation and TfR mRNA degradation (Fig. 5). Taken together, these IRE–IRP interactions, in the context of their respective mRNAs, are necessary

Figure 5 Homeostatic responses to cellular iron supply mediated by IRE–IRP interactions. Decreased iron supply activates binding of IRPs to IREs, resulting in stabilization of TfR and DCT1/Nramp2 mRNAs and translational inhibition of the mRNAs encoding ferritin (H- and L-chains), erythroid δ -aminolevulinic synthase (ALAS), mitochondrial aconitase, and Ip subunit of SDH (in *Drosophila*). This leads to increased iron uptake and transport, and reduced iron storage, erythroid utilization, and “mitochondrial activity.” Conversely, increased iron supply inactivates binding of IRPs to IREs, resulting in degradation of TfR and DCT1/Nramp2 mRNAs and translation of the mRNAs encoding ferritin (H- and L-chains), erythroid ALAS, mitochondrial aconitase, and Ip subunit of SDH (in *Drosophila*). This leads to decreased iron uptake and transport, and elevated iron storage, erythroid utilization, and “mitochondrial activity.” The stabilization of DCT1/Nramp2 mRNA by IRP binding is hypothetical and has not yet been directly shown.

and sufficient to confer iron-dependent regulation at the levels of mRNA translation and stability.

What is the mechanistic basis for these posttranscriptional regulatory events? To serve as a translational regulatory element, an IRE has to be positioned close to the 5' end of the mRNA, which contains an inverted 7-methylguanosine cap. This region is critical for the initial steps in translation. During translation initiation, a typical mRNA associates close to the cap with the 43S translation preinitiation complex, comprising the small ribosomal subunit and translation initiation factors. Subsequent to its binding, the preinitiation complex scans the 5' UTR to identify the initiation codon AUG. This is followed by joining of the large ribosomal subunit and polypeptide synthesis. Studies have revealed that IRP binding to IREs (Goossen and Hentze, 1992), or even other heterologous RNA-protein complexes (Stripeck *et al.*, 1994) located in close proximity to the 5' end of an mRNA, likely impedes translation by a steric hindrance mechanism (Gray and Hentze, 1994). Thus, an IRE-IRP complex located in a cap-proximal position effectively inhibits the stable association of the small ribosomal subunit with the initiation factor eIF4F and the assembly of 43S preinitiation complex (Muckenthaler *et al.*, 1998). Nevertheless, IRE-IRP complexes in cap-distal positions retain an impaired capacity to inhibit translation, mainly by ribosomal pausing and scanning arrest (Paraskeva *et al.*, 1999), indicative of a fine-tuning of the regulatory mechanism.

The mechanism underlying the regulation of mRNA stability by IRE-IRP interactions in the 3' UTR is less well understood. The long and complex 3' UTR of TfR mRNA contains five IREs. It appears that only three of them are required for regulation. In iron deficiency, IRP binding to these IREs appears to protect the TfR mRNA from an initial endonucleolytic attack (Binder *et al.*, 1994).

The early studies on the expression of ferritin and TfR suggested that the IRE-IRP system plays a fundamental role for the regulation of iron uptake and storage in the cell. Subsequently, it has become clear that additional mRNAs are under the control of the IRE-IRP system, and it now appears that this may also fulfill more comprehensive functions. One of them may be the control of iron utilization in erythroid cells, the major iron consumers in the body. The vast majority of iron in erythroid cells is utilized for the synthesis of heme as a constituent of hemoglobin (Ponka, 1997). The first reaction in the heme biosynthetic pathway is the condensation of glycine and succinyl-CoA to yield δ -aminolevulinic acid. This reaction is catalyzed by δ -aminolevulinic synthase (ALAS). In contrast to the housekeeping ALAS, the erythroid-specific eALAS is regulated translationally by the IRE-IRP system. The mRNA encoding eALAS contains an IRE in its 5' UTR (Cox *et al.*, 1991; Dandekar *et al.*, 1991). Even though the function of the IRE in eALAS mRNA has not yet been investigated in animal models, this IRE mediates translational control in erythroid cell culture models (Melefors *et al.*, 1993) and *in vitro* (Bhasker *et al.*, 1993). From the homeostatic point of view, the repression of eALAS translation in iron-deficient erythroid cells

would serve to prevent accumulation of excess protoporphyrin IX.

An additional, IRE-like hairpin structure has been noted in the 3' UTR of DCT1/Nramp2 mRNA (Gunshin *et al.*, 1997). This putative IRE has not been functionally characterized yet, but it may well serve as a "stability-type" IRE, as DCT1/Nramp2 mRNA levels in the duodenum are significantly increased in iron-deficient animals. It is tempting to speculate that the expression of the metal cation transporter DCT1/Nramp2, which is possibly involved in intestinal iron absorption and intracellular iron release from the endosome, may be controlled by IRE-IRP interactions.

Finally, the identification of functional IREs in mRNAs encoding polypeptides whose function appears to be less directly involved in iron metabolism suggests that the IRE-IRP system may operate as a more general posttranscriptional regulatory circuit. The mRNAs of two mitochondrial enzymes of the Krebs cycle, mammalian aconitase and insect succinate dehydrogenase (iron-sulfur subunit), both contain functional IREs in their 5' UTRs (Kohler *et al.*, 1995; Gray *et al.*, 1996; Kim *et al.*, 1996). Both aconitase and succinate dehydrogenase are iron-containing proteins involved in the regulation of cellular energy metabolism. The translational arrest of these mRNAs in the iron-deficient cell may help to prevent accumulation of the nonfunctional apoproteins.

A variety of biological activities appear to be controlled by IRE-IRP interactions. One would expect that abrogation of this genetic control may lead to disease. Indeed, a genetic defect in the IRE-IRP regulatory system has been identified in the form of the hereditary hyperferritinemia-cataract syndrome (HHCS). Patients suffering from HHCS carry mutations in L-ferritin IRE (several different mutations have been described to date), which render it functionally inactive and do not allow IRP binding (Beaumont *et al.*, 1995). The failure to control L-ferritin mRNA translation by IRPs results in the overexpression of L-ferritin and a marked increase in serum L-ferritin levels (hyperferritinemia). Even though this has no profound effects on general clinical parameters of iron metabolism, the accumulation of L-rich apoferritin in the eye lens leads to cataract formation by a currently unknown mechanism.

Iron Regulatory Proteins

The iron regulatory proteins IRP1 and IRP2 serve as the iron sensors in the cell (Henderson, 1996; Hentze and Kühn, 1996; Rouault *et al.*, 1996; Richardson and Ponka, 1997; Pantopoulos and Hentze, 1999). Both are cytoplasmic polypeptides of 98 and 105 kDa, respectively, and they belong to the family of iron-sulfur cluster isomerases (Frishman and Hentze, 1996). Their primary function is to regulate IRE-containing mRNAs. IRP1 and IRP2 were initially considered to bind to IREs with similar affinities. However, their binding affinity to some artificially engineered (Butt *et al.*, 1996; Henderson *et al.*, 1996) or natural IREs (Ke *et al.*, 1998) was found to vary substantially. IRP1, the first iron regulatory

protein to be characterized (Leibold and Munro, 1988; Rouault *et al.*, 1990), accounts for the major fraction of IRE binding activity in many tissues and cultured cells. With the exception of some cell lines, IRP1 appears to be ubiquitously expressed, whereas the levels of IRP2 usually vary between different tissues.

The best-characterized member of iron–sulfur isomerases is mitochondrial aconitase. This enzyme of the Krebs (citric acid) cycle catalyzes isomerization of citrate to isocitrate via *cis*-aconitate. The predicted amino acid sequence of human IRP1 shares ~31% identity and ~56% similarity (including conservative substitutions) with that of porcine mitochondrial aconitase (Hentze and Argos, 1991; Rouault *et al.*, 1991; Frishman and Hentze, 1996). This homology spans the entire molecule and is particularly striking (100% identity) around the catalytic core of mitochondrial aconitase, which contains a cubane 4Fe–4S cluster (Fig. 6). In this unusual iron–sulfur cluster, only three iron atoms are coordinated with Cys amino acid residues in the protein, while the fourth, Fe_a, remains coordinated to a hydroxide from solvent in a “free,” labile form. Crystallographic and biochemical studies of mitochondrial aconitase have established a direct involvement of Fe_a in the catalytic mechanism (Lauble *et al.*, 1992; Robbins and Stout, 1989a,b).

The structural similarity between IRP1 and mitochondrial aconitase has raised the possibility that IRP1 may also dis-

play aconitase activity. A series of experiments have confirmed that IRP1 is capable of assembling an aconitase-type 4Fe–4S cluster, which renders it catalytically active (Haile *et al.*, 1992a,b; Kennedy *et al.*, 1992). Indeed, IRP1 has been reidentified as the cytoplasmic homolog of mitochondrial aconitase, which was documented to exist many years ago (Guarriero-Bobyleva *et al.*, 1973). The catalytic efficiency of cytosolic aconitase is similar to that of mitochondrial (Kennedy *et al.*, 1992). However, the physiological function of an aconitase activity in the cytoplasm still remains puzzling.

The 4Fe–4S clusters in mitochondrial aconitase and IRP1 are very similar but not identical (Kennedy *et al.*, 1992). For example, in IRP1, the 4Fe–4S cluster is more stable and resistant to oxidation. In contrast, in mitochondrial aconitase, Fe_a is very labile and can be readily lost under aerobic conditions to yield 3Fe–4S. The fundamental difference between the two aconitase isoforms lies in the fact that, unlike mitochondrial aconitase, IRP1 does not continuously carry its 4Fe–4S cluster. Instead, the presence of this cluster in IRP1 strictly depends on cellular iron availability (Haile *et al.*, 1992a,b). Iron-replete cells contain 4Fe–4S IRP1, which correlates with detectable cytoplasmic aconitase and minimal IRE-binding activity. On the other hand, apoIRP1 predominates in iron-starved cells and is associated with negligible cytoplasmic aconitase and maximal IRE binding activity. In

Figure 6 Mitochondrial aconitase as a structural model for IRP1. The structure of mitochondrial aconitase and its cubane 4Fe–4S cluster are shown at left. Three compact domains (1–3) are linked to a fourth (4) via a flexible hinge region. A cubane 4Fe–4S cluster in the cleft that forms between domains 1–3 and 4 interacts with substrate (citrate). IRP1 is illustrated in an analogous structure (right) based on its extensive homology with mitochondrial aconitase. Amino acids of IRP1 identical or similar to those in mitochondrial aconitase are depicted in yellow and red, respectively. The positions of the 4Fe–4S clusters in mitochondrial aconitase and IRP1 are shown in blue. See color insert.

agreement with these observations, direct experiments employing purified or recombinant protein have demonstrated that 4Fe–4S IRP1 is the cytoplasmic aconitase, and apoIRP1 is the IRE-binding protein (Constable *et al.*, 1992; Emery-Goodman *et al.*, 1993; Gray *et al.*, 1993; Basilion *et al.*, 1994a).

Thus, unlike mitochondrial aconitase, IRP1 is a bifunctional protein with two mutually exclusive activities: one gene regulatory and another enzymatic. These activities are controlled by an unusual posttranslational iron–sulfur cluster switch (Paraskeva and Hentze, 1996), and the relatively long half-life (~ 24 hours) of IRP1 polypeptide is not affected by iron perturbations (Tang *et al.*, 1992; Pantopoulos *et al.*, 1995). The posttranslational nature of this switch is emphasized by the fact that the induction of IRE binding in iron-deficient cells does not require ongoing protein synthesis. Moreover, in extracts of iron-loaded cells, the spontaneous IRE binding activity of 4Fe–4S IRP1 is very low, but it can be fully recovered after treatment with high concentrations of reducing agents such as 2-mercaptoethanol (Hentze *et al.*, 1989), which displaces the cluster from the polypeptide backbone.

What is the structural basis for the iron–sulfur cluster switch? The crystal structure of IRP1 has not yet been solved. However, the homology between IRP1 and mitochondrial aconitase allows one to deduce information from the well-studied example of mitochondrial aconitase (Fig. 6). The latter enzyme is composed of three compact domains, linked to a fourth by a flexible hinge region. A cleft formed between domains 1–3 and domain 4 provides access to the substrate. A similar structure, possibly facilitated by the presence of the 4Fe–4S cluster, could also account for the aconitase activity of IRP1.

How does apoIRP1 then bind to IREs? Analysis of the predicted primary amino acid sequence of IRP1 did not reveal any already characterized RNA binding motifs. How-

ever, UV cross-linking (Basilion *et al.*, 1994b; Swenson and Walden, 1994; Neupert *et al.*, 1995) and protein footprinting (Gegout *et al.*, 1999) studies have identified amino acids of IRP1 that directly interact with the IRE and that are predicted to be positioned near the cleft. The “closed” structure of 4Fe–4S IRP1 would not permit access of the RNA to these IRE binding sites. To accomplish IRE binding, one has to assume that the overall structure of IRP1 may acquire a more “open” conformation, providing sufficient space in the cleft (Fig. 7). Such a structural rearrangement may be allowed by the disassembly of the 4Fe–4S cluster.

The second iron regulatory protein, IRP2, shares substantial homology with both IRP1 and mitochondrial aconitase (Frishman and Hentze, 1996). The predicted amino acid sequence of human IRP2 is 57% identical and 75% similar to that of human IRP1 (Samaniego *et al.*, 1994). However, unlike IRP1, IRP2 does not possess aconitase enzymatic activity (Guo *et al.*, 1994). Furthermore, the regulation of its IRE binding activity does not involve an aconitase-type iron–sulfur cluster and follows completely different mechanisms, in spite of the fact that IRP2 is also iron regulated: in iron-replete cells, the IRP2 polypeptide is extremely unstable, whereas iron deficiency triggers IRP2 stabilization and, in addition, *de novo* IRP2 synthesis (Guo *et al.*, 1994, 1995; Samaniego *et al.*, 1994; Henderson and Kühn, 1995; Pantopoulos *et al.*, 1995).

A particular feature of IRP2 is the insertion of 73 amino acids in the N terminus, which is necessary and sufficient to confer its iron-dependent regulation (Iwai *et al.*, 1995). This sequence contains a cysteine-rich motif that presumably directly binds iron and functions as an iron-dependent instability element. It has been suggested that binding of iron may direct site-specific oxidation of critical amino acids, which triggers ubiquitination and proteolytic degradation of IRP2 by the proteasome pathway (Iwai *et al.*, 1998) (Fig. 8).

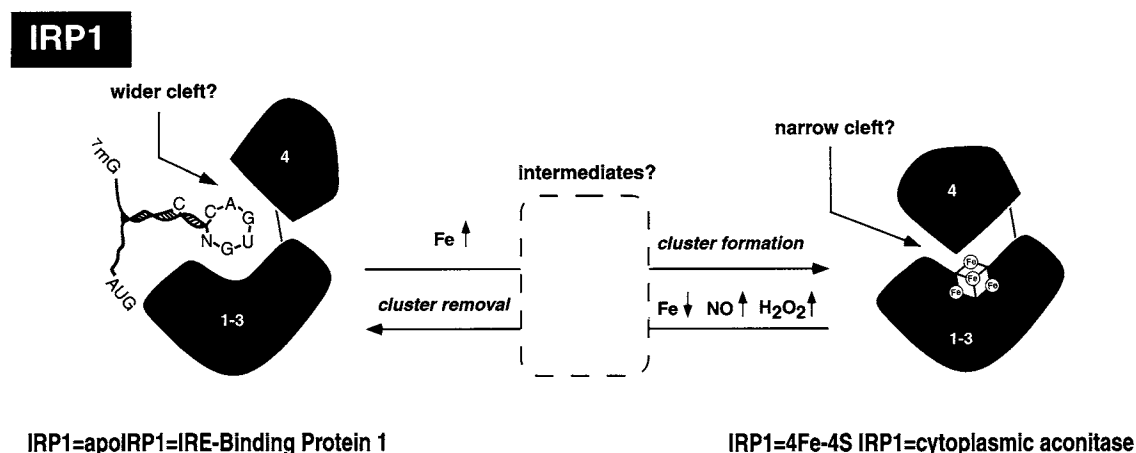

Figure 7 Posttranslational regulation of bifunctional IRP1 in response to iron, NO, and H_2O_2 is mediated by an iron–sulfur cluster switch. In iron-replete cells IRP1 assembles a cubane 4Fe–4S cluster. Iron starvation, NO, and H_2O_2 trigger the switch of 4Fe–4S to apoIRP1, resulting in the conversion of cytosolic aconitase to IRE binding protein.

Figure 8 Regulation of IRP2 at the level of protein stability. Iron starvation and NO result in *de novo* synthesis and stabilization of IRP2. Increase in iron levels triggers oxidation of critical cysteine residues that tags IRP2 for degradation by the proteasome, following ubiquitination.

Nitric Oxide Modulates Iron Regulatory Proteins

The capacity of NO to interact with iron, among various other targets, chemically links NO biology with iron metabolism. The resulting iron–nitrosyl complexes are paramagnetic and can be studied by electron paramagnetic resonance (EPR) spectroscopy (Drapier *et al.*, 1991; Kubrina *et al.*, 1992; Henry *et al.*, 1993; Bastian *et al.*, 1994; Lee *et al.*, 1994). There is no restriction on specific forms of iron to constitute a target of NO. Thus, NO readily reacts with low-molecular-weight iron chelates, and it reacts with heme iron or iron–sulfur clusters in metalloproteins. The well-documented effect of NO to promote smooth muscle relaxation is based on the activation of a guanylyl cyclase by binding of NO to the heme iron of its catalytic site (McDonald and Murad, 1996). Presumably, NO binding elicits an allosteric change in guanylyl cyclase, which leads to increased cGMP synthesis and the concomitant activation of signaling pathways. On the other hand, NO may also negatively modulate the activity of iron-containing proteins. Stimulated macrophages release NO, generated by the inducible NOS2, to inactivate vital iron-containing proteins in target cells. The iron–sulfur clusters in complexes of the respiratory chain, NADH:ubiquinone oxidoreductase and NADH:succinate oxidoreductase, are presumed to be sites of targeted inactivation by NO (Drapier and Hibbs, 1986; Hibbs *et al.*, 1988). As an iron–sulfur protein, mitochondrial aconitase is also sensitive to inactivation by NO (Drapier and Hibbs, 1986; Gardner *et al.*, 1997; Hibbs *et al.*, 1988; Castro *et al.*, 1998).

The 4Fe–4S cluster of IRP1 is more stable than that of mitochondrial aconitase (Kennedy *et al.*, 1992). However, the overall sensitivity of iron–sulfur proteins to NO, and in addition the ability of NO (in form of NO⁺) to engage in nitrosylation reactions and control the function of various proteins, raised the intriguing possibility that NO might also regulate IRP1 and therefore control cellular iron metabolism. Early experiments employing immunologically stimulated murine primary peritoneal macrophages or macrophage-like cell lines demonstrated that NO biosynthesis correlates with

activation of IRP1 (to bind to IREs) and with repression of ferritin mRNA translation (Drapier *et al.*, 1993; Weiss *et al.*, 1993). At the time the initial results were obtained, IRP2 had been very poorly characterized. Nevertheless, it is noteworthy that in some of these experiments a clear activation of IRP2 can be observed (murine IRP2 migrates faster than IRP1 in electrophoretic mobility shift assays) (Weiss *et al.*, 1993). The described effects are antagonized by N^G-methyl-L-arginine, a stereospecific inhibitor of NO synthase, suggesting the involvement of NO in modulation of the IRE–IRP regulatory system.

A series of additional experimental approaches have confirmed that NO exerts a signaling activity on the IRE–IRP regulatory system. First, nonerythroid or erythroid cell lines were exposed to NO, generated intracellularly from a stably transfected NOS2 transgene (Pantopoulos and Hentze, 1995a; Rafferty *et al.*, 1996; Domachowske *et al.*, 1996). Alternatively, NO was administered to target cells from the outside, either by pharmacological donors (Oria *et al.*, 1995; Richardson *et al.*, 1995; Pantopoulos *et al.*, 1996) or by coculture with the NOS2 transfectants (Pantopoulos *et al.*, 1996). Heterologous expression of NOS2 results in a NO-dependent activation of IRP1 and IRP2 (Pantopoulos and Hentze, 1995a). As expected, this is associated with repressed ferritin biosynthesis and increased Tfr mRNA levels. In addition, the erythroid cells expressing NOS2 display a profound inhibition of hemoglobin expression, most likely due to inhibition of eALAS mRNA translation (Domachowske *et al.*, 1996). Similar results have been obtained with cells treated with NO-liberating drugs (Richardson *et al.*, 1995; Pantopoulos *et al.*, 1996) and with cells cocultured with NOS2 transfectants (Pantopoulos *et al.*, 1996). Thus, NO has been demonstrated to activate IRP1 and IRP2 by intra- and intercellular means and to affect the expression of IRE-containing mRNAs. Taken together, NO modulates iron metabolism by both intracellular and intercellular signaling to the IRE–IRP regulatory system (Figs. 7 and 8).

The growing interest in the regulatory connection between the NO and IRE–IRP pathways has prompted studies

to investigate the mechanism of NO action. Exposure of highly purified bovine mitochondrial and cytosolic aconitase (4Fe–4S IRP1) preparations to authentic NO gas or to spermine NONOate results in the rapid inactivation of both enzymes, even in the presence of aconitase substrate (Kennedy *et al.*, 1997). A spectroscopic analysis by EPR showed that the 4Fe–4S clusters of aconitases are targets of NO attack (Kennedy *et al.*, 1997). The interaction with NO *in vitro* yields two major types of signals, at $g = 2.02$, corresponding to a 3Fe–4S cluster, and at $g \approx 2.04$, characteristic of dinitrosyl–iron–dithiol–protein complexes. Under these conditions, there is no strict order of appearance for the above EPR signals. Moreover, the appearance of the $g = 2.02$ signal of a 3Fe–4S cluster is not proportional to the loss of enzymatic activity. This strongly suggests that the inactivation of aconitase by NO is not exclusively based on the conversion of the 4Fe–4S cluster to 3Fe–4S by loss of Fe_a, but rather is a result of a more general cluster disassembly beyond the 3Fe–4S stage. Furthermore, this disassembly does not seem to require the formation of a 3Fe–4S intermediate. In contrast to NO, other more potent oxidants, such as peroxynitrite and superoxide, are able to remove Fe_a and yield 3Fe–4S inactive aconitases. In this case, aconitase substrates afford protection to the 4Fe–4S cluster against oxidation. As expected from previous results, the oxidative removal of the comparatively more stable Fe_a in IRP1 requires higher doses of peroxynitrite or superoxide.

In agreement with the data obtained with purified bovine aconitases, the treatment of iron-loaded human recombinant IRP1 with authentic NO gas is sufficient to completely abolish the enzymatic aconitase activity (Drapier *et al.*, 1993). However, this treatment leads to only a partial (20%) activation of IRE binding. NO-mediated partial induction of IRE binding has also been obtained with crude cytoplasmic extracts exposed to NO-releasing drugs (Jaffrey *et al.*, 1994). These *in vitro* data are fully consistent with the spectroscopic analysis and with the idea that NO itself is capable of attacking and dissociating the 4Fe–4S cluster in IRP1. However, it is still unclear whether the activity of NO per se is sufficient to completely disassemble and remove the 4Fe–4S cluster, to yield apoIRP1. The situation is more clear for peroxynitrite or superoxide: these oxidants inactivate aconitase *in vitro* (Bouton *et al.*, 1996, 1997) by converting 4Fe–4S to 3Fe–4S IRP1 (Kennedy *et al.*, 1997), an intermediate which also fails to perform as an IRE binding protein.

These *in vitro* approaches have provided some valuable insights concerning the chemical interaction of NO with IRP1, but they have not resolved the mechanism of the NO-mediated activation of IRE binding. Moreover, these studies are only partly informative with regard to the effects of NO on the regulation of iron metabolism in the living cell. Cell culture experiments with stimulated macrophages or stable NOS2 transfectants have established that NO exerts profound effects on cellular iron metabolism (Drapier *et al.*, 1993; Weiss *et al.*, 1993; Pantopoulos and Hentze, 1995a; Rafferty *et al.*, 1996; Domachowske *et al.*, 1996). However, secondary effects caused by the stimulation of macrophages

or by the constitutive biosynthesis of NO caution against far-reaching mechanistic interpretations. Thus, employing a well-defined and controlled system to generate NO might be more appropriate to reconstitute the series of molecular events taking place in the IRE–IRP regulatory system in response to NO signaling.

There is a broad range of compounds that release NO in solution and have therefore been routinely used as pharmacological NO donors. The choice of a suitable NO-releasing drug is very important to address the signaling of NO to the IRE–IRP system. The minimal prerequisites for such drug would be a relative stability and linear release of NO under the experimental conditions. In addition, the metabolites arising after the liberation of NO should not affect iron metabolism. *S*-Nitroso-*N*-acetyl-D,L-penicillamine (SNAP) is widely used as an NO donor and appears to fulfill these criteria: it is quite stable, and 100 μM SNAP yields $\sim 1.4 \mu\text{M}/\text{min}$ NO in a near-linear fashion at 37°C (Feelisch, 1991). Moreover, NO release by SNAP in solution is rapid and can be easily followed by measuring nitrite levels. Treatment of cultured murine B6 fibroblasts with 100 μM SNAP for 4 or 8 hours results in the induction of IRP1 to bind to IREs, whereas the SNAP precursor D,L-penicillamine does not exhibit any effects (Pantopoulos *et al.*, 1996). SNAP also elicits the activation of IRP1 in other cell lines, including rat hepatoma FTO2B (Phillips *et al.*, 1996) and human erythroleukemia K562 (Richardson *et al.*, 1995). Moreover, the treatment of K562 cells with SNAP results in increased TfR mRNA levels and enhanced iron uptake from transferrin (Richardson *et al.*, 1995). Positive results on IRP1 activation have also been obtained with the NO-donors hydroxy-2-oxo-3,3-bis(3-aminoethyl)-1-triazene (NOC-18) (Pantopoulos *et al.*, 1996) and hydroxy-2-oxo-3-(*N*-ethyl-3-aminoethyl)-3-ethyl-1-triazene (NOC-12) (Castro *et al.*, 1998).

In contrast to SNAP and NOC-18, sodium nitroprusside (SNP) and 3-morpholinosydnonimine (SIN-1) have no effect on IRP1 when administered to the B6 fibroblasts (Pantopoulos *et al.*, 1996), and the agents also fail to stimulate iron uptake and TfR mRNA stabilization in K562 cells (Richardson *et al.*, 1995). SNP is widely used as a nitrosylating agent because it liberates the nitrosonium cation NO⁺, which forms nitrosothiols with cysteine sulfhydryl groups in proteins. On the other hand, the decomposition of SIN-1 yields NO and superoxide, which readily react to form peroxynitrite. These data appear to support the view that, in living cells, NO is the actual activator, whereas the redox derivatives NO⁺ and peroxynitrite are ineffective in signaling to IRP1. Assuming that inside the cell 4Fe–4S IRP1 is very likely bound to citrate (present in a molar excess), the above results are consistent with the *in vitro* spectroscopic data showing that aconitase substrates protect the 4Fe–4S cluster from oxidation by peroxynitrite (or superoxide) but fail to prevent NO-mediated cluster disassembly (Kennedy *et al.*, 1997).

Another murine fibroblast cell line, Ltk[–], has been employed as a model system for studying signaling of NO to

Figure 9 Kinetic analysis reveals differential responses of iron regulatory proteins to H_2O_2 , iron starvation, and NO. Ltk⁻ murine fibroblasts were left untreated (lane 1) or were treated with 100 μM H_2O_2 for 0.5, 1, 2, 4, 6, or 8 hours (lanes 2–7, respectively), with 100 μM desferrioxamine (iron chelator) for 0.5, 1, 2, 4, 8, or 12 hours (lanes 8–13), or with 100 μM SNAP (NO-releasing drug) for 0.5, 1, 2, 4, 8, or 12 hours (lanes 14–19). H_2O_2 and SNAP were replaced with fresh solutions after 4 and 6 hours, respectively. Cytoplasmic extracts (25 μg) were analyzed by electrophoretic mobility shift assay with 25,000 cpm ^{32}P -labeled IRE probe in the absence (top) or presence (bottom) of 2% 2-mercaptoethanol (2-ME). The positions of IRE/IRP1 and IRE/IRP2 complexes and of excess free IRE probe are indicated by arrows. Reproduced, with permission, from Pantopoulos, K., Weiss, G., and Hentze, M. W. (1996). Nitric oxide and oxidative stress (H_2O_2) control mammalian iron metabolism by different pathways. *Mol. Cell. Biol.* **16**, 3781–3788.

the IRE–IRP system. These cells express significant levels of IRP2, in addition to IRP1. A comparative analysis (Pantopoulos *et al.*, 1996) showed that both IRP1 and IRP2 in Ltk⁻ cells are activated in response to iron starvation and NO exposure, following pharmacological treatment with the iron chelator desferrioxamine or with SNAP, respectively. Moreover, the activation by the two stimuli displays remark-

ably similar kinetics: desferrioxamine and SNAP trigger a partial activation of both IRP1 and IRP2 after 4 hours of treatment, whereas maximal activation is observed within 8 to 12 hours (Fig. 9). In contrast to IRP1, IRP2 activation by iron starvation or NO is blocked by inhibitors of protein synthesis. Another interesting aspect of NO signaling to IRPs is that NO should be present during the course of the

tive regulation (Recalcati *et al.*, 1998). The negative results have been obtained with cytokine-treated cell lines. These discrepancies could be explained on the basis of variabilities between different cell lines, different responses to various redox species of NO, and the pleiotropic effects of cytokines, but in some reports the lack of appropriate positive controls for IRP2 activation is also evident.

Regulation of Iron Metabolism by Oxidative Stress

The regulation of iron metabolism by NO has established that iron is not the only signal for the IRE–IRP system, which raises the possibility that additional signals may exist. On the basis of similarities with NO (discussed at the beginning of this chapter), potential other regulators can be found among the family of the reactive oxygen intermediates (ROIs). The ability of ROIs to inactivate bacterial and mitochondrial aconitases by targeting their iron–sulfur clusters (Gardner and Fridovich, 1991; Gardner *et al.*, 1995) is another feature which made them attractive as potential regulators of IRP1. Thus, in the context of oxygen-dependent iron toxicity, it was very interesting to investigate whether oxidative stress has any effects in the regulation of cellular iron homeostasis.

A first direct regulatory link between iron metabolism and oxidative stress was established with the finding that treatment of cultured cells with micromolar concentrations of H_2O_2 leads to the activation of IRP1 (Martins *et al.*, 1995; Pantopoulos and Hentze, 1995b). The induction of IRE binding is associated with a concomitant loss of aconitase activity (Fig. 7). A series of experiments have shown that H_2O_2 constitutes a distinct signal to the IRE–IRP regulatory system (Pantopoulos *et al.*, 1996). In contrast to NO and to iron chelation, H_2O_2 elicits a rapid induction of IRP1 within 30 to 60 min (Fig. 9), suggesting a different mechanistic basis for the iron–sulfur cluster switch. In addition, whereas NO and iron chelation activate both IRP1 and IRP2, the H_2O_2 signal is specific for IRP1. This stress-induction of IRP1 is biphasic, and the presence of H_2O_2 does not need to be sustained during the course of the treatment: a short pulse of cells with a bolus of 100 μM H_2O_2 for 15 min, followed by a wash and removal of the inducer, is sufficient to elicit a complete, long-lasting (over 4 hours) activation of IRP1 (Pantopoulos *et al.*, 1996). In agreement with this, a very sensitive chemiluminescence technique for H_2O_2 determination has shown that extracellular H_2O_2 decays rapidly in the medium of cultured cells, without compromising the effects on IRP1 (Pantopoulos *et al.*, 1997).

Can the switch of cytosolic aconitase to IRE-binding protein in response to oxidative stress be attributed to a direct removal of the 4Fe–4S cluster by H_2O_2 or other ROIs? As mentioned in the previous section of this chapter, reactive oxygen species (including superoxide, H_2O_2 , and peroxynitrite) can oxidize 4Fe–4S to 3Fe–4S IRP1 *in vitro*. This leads to inactivation of aconitase but is not sufficient to induce IRE binding. Thus, in contrast to the effects observed in intact

cells, treatment of crude cytoplasmic extracts or iron-loaded recombinant IRP1 with H_2O_2 does not activate the IRE-binding activity of IRP1 (Martins *et al.*, 1995; Pantopoulos and Hentze, 1995b; Brazzolotto *et al.*, 1999). Moreover, *in vitro* treatments with excess of ROIs may lead to complete inactivation of IRE binding, possibly as a result of IRP1 oxidation (Cairo *et al.*, 1996; Pantopoulos and Hentze, 1998).

The development of redox-sensitive probes to monitor intracellular levels of ROIs by fluorescence-activated cell sorting has helped to address these questions in cell culture models. Employment of such techniques has shown that a mere increase in intracellular levels of ROIs is not sufficient to activate IRP1. For example, pharmacological inhibition of catalase, a major H_2O_2 -degrading enzyme, results in intracellular accumulation of H_2O_2 , but this does not affect IRE binding activity (Pantopoulos *et al.*, 1997). An activation of IRP1 in response to intracellular oxidative stress has been observed after a treatment of cells with antimycin A, an inhibitor of complex III in the respiratory chain. Even though this treatment results in a rapid, detectable leakage of ROIs from mitochondria, IRP1 activation significantly lags behind the generation of ROIs (at least 90 min) and is not antagonized by antioxidants (Pantopoulos *et al.*, 1997). In agreement with the *in vitro* data, high levels of intracellular oxygen radicals may even completely inactivate IRP1; this is evident after treatment of cells with menadione, a redox cycling quinone. Whereas low doses of menadione partially activate IRP1 and trigger an incomplete Fe–S cluster switch, high doses cause a severe intracellular oxidative stress, which ultimately leads to the irreversible damage of both the cytoplasmic aconitase as well as the IRE binding activity of IRP1 (and IRP2) (Gehring *et al.*, 1999). The complexity of the IRP responses to intracellular oxidative stress is emphasized by the partial activation of IRP1 after a treatment of cells with paraquat, another redox cycling drug (Pantopoulos and Hentze, 1995b; Gehring *et al.*, 1999).

These data suggest that the rapid activation of IRP1 in response to extracellular H_2O_2 is not a result of a direct attack of the Fe–S cluster by ROIs. In agreement with this notion, when a bolus of H_2O_2 is administered to cells from the outside, the activation of IRP1 is not associated with a concomitant increase in intracellular levels of ROIs (Pantopoulos *et al.*, 1997). Thus, extracellular H_2O_2 most likely triggers a signaling pathway that results in the activation of IRP1. In contrast to the delayed effects of iron starvation and NO, this stress response leads to the accelerated turnover of the 4Fe–4S cluster in IRP1. Although the slow switch of 4Fe–4S to apoIRP1 by iron starvation and NO could be spontaneous, it is likely that the rapid removal of the cluster in response to H_2O_2 signaling could be assisted by other cluster-destabilizing factors.

A recently established *in vitro* system has provided more direct evidence that an oxidative stress-response program activates IRP1 (Pantopoulos and Hentze, 1998). B6 fibroblasts, permeabilized with the bacterial toxin streptolysin-O (SLO), retain their ability to activate IRP1 by H_2O_2 . This activation follows the same biphasic kinetics as in intact

cells, and it requires the presence of noncytoplasmic, possibly membrane-associated components. Moreover, IRP1 activation can be blocked by addition of ATP γ S and GTP γ S or by treatment with calf intestinal alkaline phosphatase. Our current model for the H₂O₂-induced activation of IRP1 postulates that a (possibly plasma) membrane-associated factor senses extracellular H₂O₂ and relays the signal to the cytoplasm by a signaling pathway that results in the switch of 4Fe–4S to apoIRP1 (Fig. 11).

Conclusions

The regulation of iron metabolism by NO and ROIs via the IRPs may have significant pathophysiological implications, especially in the context of inflammation. To inactivate invading pathogens, immune effector cells such as macrophages and neutrophils are stimulated to release NO and reactive oxygen species (Baggiolini and Thelan, 1991; Hampton *et al.*, 1998). These responses are thought to directly target crucial iron-containing enzymes of the pathogens. The novel regulatory links described in this chapters

suggest that NO and oxidative stress may also control iron metabolism in immune effector cells and, in addition, in tissues.

The release of NO and reactive oxygen species (including H₂O₂) under inflammatory conditions is predicted to activate IRPs and lead to an increase in cellular iron uptake via the TfR. This putative shift of iron from the circulation into cells may serve to deprive the invading bacteria of iron, which is essential for their growth. In macrophages, increased levels of intracellular iron may enhance the cytotoxic potential by Fenton/Haber–Weiss reactions in the controlled environment of the phagosome. The rapid shutoff of ferritin synthesis in response to the activation of IRPs may help to sustain cytotoxic conditions. The negative effects of some proinflammatory cytokines on TfR expression (Bourgeade *et al.*, 1992; Pantopoulos and Hentze, 1995a; Weiss *et al.*, 1997) could serve to balance iron uptake independently of the status of IRPs. Moreover, IRPs could also compromise these responses: accumulation of iron above a critical threshold inside the cells would switch apo to 4Fe–4S IRP1 and destabilize IRP2. On the other hand, it is very likely that, under certain circumstances, NO may have the potential to

Figure 11 A model for the pathway of IRP1 activation by extracellular H₂O₂. The cell “senses” increased levels of extracellular H₂O₂ by a putative plasma-membrane associated factor. The relayed H₂O₂ signal leads to the activation of IRP1 by dissociation of its 4Fe–4S cluster. This signaling cascade is blocked by dephosphorylation, ATP γ S, GTP γ S, and sodium azide. The involved sensor, signaling factors, and mechanism of 4Fe–4S cluster removal remain to be identified.

antagonize oxygen-mediated toxicity. In tissue culture models, formation of heme or nonheme iron–nitrosyl complexes can protect cells from oxidative injury (Gorbunov *et al.*, 1997), most likely due to inactivation of the ability of iron to engage in Fenton-type reactions.

Of particular interest for the regulatory link between iron metabolism and NO biology is the control of NOS2 expression in response to iron levels. In addition to various immunological stimuli, iron starvation triggers a transcriptional activation of NOS2 biosynthesis (Weiss *et al.*, 1994). This would lead to NO-mediated activation of IRPs and enhanced cellular iron uptake. The increase in intracellular iron would not only inactivate IRPs, but also inhibit NOS2 expression in an autoregulatory loop. It has been suggested that disturbances in this control loop caused by constitutive cytokine-induced expression of NOS2 may contribute to the development of the “anemia of chronic disease,” which is associated with chronic inflammation (Weiss *et al.*, 1995). The hallmark of this disorder is a remarkable increase in iron stores (mirrored in serum ferritin) and reduced iron availability for erythropoiesis.

An increase in intracellular iron concentration under conditions of oxidative stress is considered to aggravate iron toxicity. To speculate on the contribution of the stress regulation of IRP1 to these phenomena, a distinction between extra- and intracellular oxidative stress should be made. IRP1 is clearly activated in response to extracellular H₂O₂. This may have important consequences in the context of inflammation. Moreover, in pathological conditions associated with oxidative stress, such as the ischemia–reperfusion injury that accompanies heart attacks and strokes, IRP1 activation may contribute to iron-mediated tissue damage. The decreased oxygen supply during hypoxia causes the inactivation of many enzymes involved in detoxification of oxygen radicals. A lag between reoxygenation and upregulation of these enzymes in the reperfusion phase results in the uncontrolled intracellular generation of oxygen radicals (Zweier *et al.*, 1988, 1994) and, possibly, extracellular release of readily diffusible H₂O₂. Experimental data suggest that a transient (10–15 min) increase in extracellular H₂O₂ levels above 10 μ M would lead to a prolonged state of IRP1 activation (Pantopoulos *et al.*, 1996). Moreover, IRP1 and IRP2 were found to be activated in response to hypoxia/reperfusion in different culture models (Hanson and Leibold, 1998; Hanson *et al.*, 1999; Toth *et al.*, 1999). An IRP-mediated inhibition of ferritin biosynthesis would then reduce iron storage and detoxification and thus may promote cell damage by favoring Fenton chemistry.

The high sensitivity of IRP1 to extracellular H₂O₂ emphasizes that ROIs not only are toxic by-products, but also exert signaling functions that potentially affect additional targets. Some of them have already been identified. An additional example is the transcription factor NF- κ B, which responds to a variety of environmental stimuli, including oxidative stress, and activates the transcription of multiple genes (Baeuerle and Henkel, 1994). Thus, the consequences of IRP1 activation by H₂O₂ should not be viewed in isolation

but considered in a more general context. Nevertheless, the conservation of the IRP1 stress-response to extracellular H₂O₂ in different cell types and species suggests that this pathway may have important physiological implications for the regulation of iron metabolism in the body.

The regulation of iron metabolism is intimately connected with the biochemistry of NO and oxygen radicals. As in numerous other examples, dissection and elucidation of these biochemical pathways at the molecular level are prerequisite to understanding the pathophysiological implications.

Redox Modulation of Iron Regulatory Proteins by Nitric Oxide and Peroxynitrite

Jean-Claude Drapier, Cécile Bouton, and Leonor Oliveira

*Institut de Chimie des Substances Naturelles
CNRS, Gif-sur-Yvette, France*

IRON REGULATORY PROTEINS (IRP1 AND IRP2) BIND TO IRON-RESPONSIVE ELEMENT(S) (IRE) IN THE UNTRANSLATED REGION OF SEVERAL MRNAs ENCODING PROTEINS INVOLVED IN IRON METABOLISM AND ENERGY PRODUCTION. IRP1 IS A BIFUNCTIONAL PROTEIN THAT ALSO DISPLAYS ACONITASE ACTIVITY WHEN IT CONTAINS AN INTACT [4Fe–4S] CLUSTER. IRP2 HAS NO Fe–S CLUSTER BUT EXHIBITS SEVERAL REDOX-SENSITIVE CYSTEINES. IN THIS REVIEW, WE DESCRIBE, COMPARE, AND EXPRESS OUR VIEWS ON THE RESPECTIVE EFFECTS OF NITRIC OXIDE (NO) AND PEROXYNITRITE ON THESE TWO CHEMOREACTIVE PROTEINS. DATA ARE DISCUSSED IN THE MORE GENERAL CONTEXT OF THE SENSITIVITY OF IRPs TO CHEMICAL MESSENGERS INCLUDING OXYGEN-DERIVED SPECIES. WE DESCRIBE TWO LATENT FORMS OF IRP1 WHOSE EXISTENCE FURTHER COMPLICATES THE PICTURE, AND WE REVIEW THE REQUIREMENT FOR REDUCTION PRIOR TO BINDING IRE. ENDOGENOUS PRODUCTION OF NO READILY TRIGGERS THE ACONITASE–RNA BINDING SWITCH. *IN VITRO* STUDIES REVEALED THAT IN SO DOING NO REACTS RAPIDLY WITH IRP1 BUT REQUIRES COOPERATION WITH THE THIOREDOXIN SYSTEM. PEROXYNITRITE, AS A STRONG OXIDANT, MOSTLY LIMITS ITS CAPACITIES TO INACTIVATION OF ACONITASE ACTIVITY, WITHOUT SIMPLE TRIGGERING OF IRE BINDING. WE OBSERVED THAT IRP2 REGULATION IS OPPOSITE TO THAT OF IRP1 IN STIMULATED MACROPHAGES. PEROXYNITRITE ALSO DECREASES IRP2 ACTIVITY AT A POSTTRANSLATIONAL LEVEL. DOWNREGULATION OF IRP2 MAY BE RELEVANT FOR BALANCING IRP1 INTERFERENCE IN IRON HOMEOSTASIS.

Introduction

The notion of nitric oxide (NO)-mediated redox modulation has emerged in the mid-1990s. NO and related species are prototypical effectors of this distinctive signaling pathway, which proceeds through covalent bonding and involves redox biochemistry (Stamler, 1994; Drapier and Bouton, 1996). This novel type of signaling relies on the interplay between two partners: a reactive effector and a sensor molecule (hormone or protein) able to respond to the chemical

signal by adapting its function to the covalent modifications and/or structural change. In most cases, the submolecular targets that perceive the chemical message are redox active sulfhydryl groups and transition metals, especially iron. The list of proteins sensitive to redox modulation by NO and related species is growing rapidly (Broillet, 1999). Here, we will focus on the interplay between NO or peroxynitrite with iron regulatory protein 1 (IRP1) and IRP2, two RNA-binding proteins that regulate vertebrate cell iron metabolism (see also Bouton, 1999). Iron is essential for survival of most

living organisms, but it has two major drawbacks: low solubility and production of harmful products via the Fenton reaction. It is therefore essential for cells to fine-tune transport, uptake, and storage of iron. In mammals, the transferrin receptor and ferritin are chiefly responsible for iron uptake and sequestration, respectively. Cellular iron status is controlled by sound expression of transferrin receptor and ferritin through expression and activity of IRPs. Regulation of IRP activities has been the subject of numerous studies. We shall outline the background of such studies, and we compare the effects of NO and peroxynitrite.

IRPs and Aconitases: Two Merging Stories

IRP1 and IRP2 maintain the homeostasis of intracellular iron through a posttranscriptional mechanism. They recognize specific sequences called iron responsive elements (IREs) on distinctive mRNA (Leibold and Munro, 1988). IREs are stem-loops made up of ~30 nucleotides and consist of a stable stem about 10 nucleotides long with a bulged cytosine residue and a loop with the conserved sequence CAGUGN (Theil, 1998). Functional IREs have been found in the 5' untranslated region of mRNA of human ferritin H- and L-chains (Aziz and Munro, 1987; Hentze *et al.*, 1987), δ -aminolevulinate synthase of erythroid cells (Dandekar *et al.*, 1991), mitochondrial aconitase (Zheng *et al.*, 1992; Kim *et al.*, 1996), and subunit b of *Drosophila melanogaster* succinate dehydrogenase (Kohler *et al.*, 1995; Gray *et al.*, 1996; Melefors, 1996). IRP-IRE interaction in the 5' untranslated region inhibits translation (Gray and Hentze, 1994). In contrast, when IRPs bind to IRE(s) at the 3' end of mRNA, the binding stabilizes the message, probably by preventing endonucleotide degradation (Fig. 1) (see Klausner *et al.*, 1993, Rouault and Klausner, 1997, and Kühn, 1998, for reviews). Transferrin receptor mRNA contains five IREs, all located at its 3' end, and the interaction between IRPs and IREs increases the stability of its mRNA. An iron transporter named "divalent-metal transporter" (DMT1, also known as DCT1/Nramp2) has been characterized (Gushin *et al.*, 1997). It is expressed ubiquitously but preferentially in the duodenum. DCT1/Nramp2 mRNA contains an IRE-like sequence in its 3' untranslated region, which strongly suggests that it could also be controlled by IRPs.

In the late 1980s, IRP1, which has previously been referred to as FRP, P90, IRF, or IRE-BP, was identified as an RNA-binding protein that regulates vertebrate cell iron metabolism. A few years later, comparison of the amino acid sequences of pig heart aconitase and IRP1 revealed high identity (~30%) between porcine mitochondrial aconitase and human IRP1. Eventually, it was disclosed that the same polypeptide carries both activities. IRP1 was therefore acknowledged as a bifunctional protein, either cytosolic aconitase or RNA-binding protein (Hentze and Argos, 1991; Rouault *et al.*, 1991; Kaptain *et al.*, 1991; Kennedy *et al.*, 1992). IRP1 thus belongs to the iron-sulfur (Fe-S) isomerase family, which contains fungal and bacterial isomerases

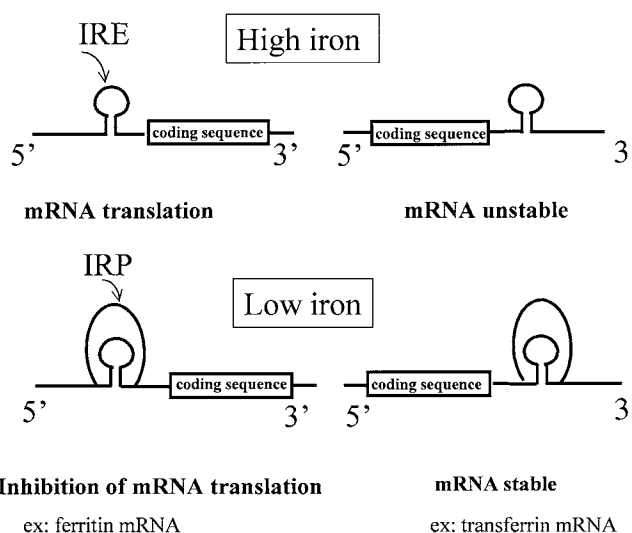

Figure 1 Schematic representation of the posttranscriptional regulation mediated by IRPs. In cells depleted of iron, IRP1 and IRP2 bind equally well to the IRE stem-loop structures found in the untranslated regions of different mRNA. The binding of IRP to an IRE in the 5' end of mRNAs represses their translation. In contrast, the binding of IRP to at least three of the five IREs at the 3' end of transferrin receptor mRNAs protects it from endonucleolytic degradation.

involved in leucine biosynthesis and aconitases (Frishman and Hentze, 1996; Gruer *et al.*, 1997).

Fe-S proteins were identified and recognized in the 1960s. They participate in several basic metabolic pathways of living organisms including photosynthesis, nitrogen fixation, and oxidative phosphorylation. Fe-S clusters are very ancient prosthetic groups that, in many cases, are involved in oxidoreduction reactions. Aconitases are monomeric proteins (M_r 68,000–120,000) containing a single Fe-S cluster that stands out because it binds substrate at the active site (Beinert and Kennedy, 1989). They convert citrate to isocitrate, with *cis*-aconitate as an intermediate. Porcine heart mitochondrial aconitase was crystallized by Stout and co-workers (Robbins and Stout, 1989; Lauble *et al.*, 1992) (Fig. 2). It thus became the prototypic aconitase, and valuable information on the active site was derived from these studies. This aconitase will hereafter be referred to as mt-aco. As IRP1 resembles mt-aco in the predicted domain structure, we will digress on what we can learn from the crystal structure of the latter. Mt-aco is an 83-kDa monomer arranged in four domains, with three structural domains packed around a [4Fe-4S] cluster and connected to the fourth domain by a linker peptide. The [4Fe-4S] cluster is thus located within a cleft which divides the packed domains 1–3 from domain 4. One specific iron of the cluster (Fe_a) is not connected to the protein backbone but is held by the α (isocitrate) or β (citrate) carboxyl of the hydrated substrates. In addition, the hydroxyl of citrate or isocitrate also binds Fe_a . This iron atom of the cluster is thus involved in the enzymatic catalysis, and its removal is sufficient to abolish activity (Beinert and Kennedy, 1989). Such a cluster is exposed to the solvent

Figure 2 Structure of the [3Fe-4S] cluster-containing pig mitochondrial aconitase crystallized by Robbins and Stout (1989). From SWISS-PROT protein database. See color insert.

and hence vulnerable to environmental signals such as NO (Drapier, 1997). Analysis combining electron paramagnetic resonance (EPR) and Mössbauer spectroscopy revealed that $[4\text{Fe}-4\text{S}]^{2+}$ -containing mt-aco is the enzymatically active form. The three other iron atoms are held to the protein by cysteine residues at positions 358, 421, and 424.

IRP1 and mt-aco exhibit approximately 31% identity and about 56% similarity. As deduced from sequence alignment and computer prediction, IRP1, like mt-aco, comprises four domains, three at the N-terminal end which form a compact core (domains 1–3), to which the fourth (domain 4) is connected by a peptide linker. The flexibility of this hinge allows fields 1–3 and 4 to come together around a narrow cleft corresponding to the active site of the enzyme. The $[4\text{Fe}-4\text{S}]$ center is located in the cleft and is linked to domain 3 by cysteines 437, 503, and 506 (Fig. 3). Fe_a interacts with substrates, for example, citrate, which itself binds to at least four arginines (R536, R541, R699, R780) in human IRP1 belonging to the four domains. Thus the presence of the substrate at the catalytic site contributes to the stabilization of the protein structure and to the connection of domains 1–3 to domain 4 (Beinert and Kennedy, 1993). IRP1 in this closed conformation (holo-IRP1) exhibits aconitase activity in the cytosol.

IRP2, whose sequence in humans exhibits 57% identity with and 75% similarity to that of IRP1 (Henderson, 1996), was also categorized as an aconitase, even though it has no Fe-S cluster and hence no enzymatic activity.

Measurement of IRP Activities

Aconitase assays have been extensively described elsewhere (Fansler and Löwenstein, 1969; Drapier and Hibbs, 1996). Two spectrophotometric assays are routinely used. One relies on the UV absorbance of *cis*-aconitate at 240 nm. The other is performed in the presence of isocitrate dehydrogenase, which catalyzes the oxidation of citrate to α -ketoglutarate coupled with the reduction of NADP at 340 nm. RNA-binding activity of IRPs is determined by an electrophoretic mobility shift assay, which was originally described by Leibold and Munro (1998) and has since been modified (Müllner *et al.*, 1989; Drapier and Hibbs, 1996). Briefly, a $[^{32}\text{P}]\text{CTP}$ -labeled IRE probe is prepared, generally from a plasmid containing the IRE sequence of human ferritin H-chain mRNA. After incubation of a molecular excess of probe (this is a crucial point) with cell lysate or purified protein, complexes between IRPs and IRE are separated from unbound probe on a 6% polyacrylamide gel. The two IRPs from rat, or mouse, migrate separately (Fig. 4). When human cells are analyzed, IRP1 and IRP2 comigrate and can be discriminated only by a supershift assay. Two percent 2-mercaptoethanol (2-Me) is routinely added to each sample prior to the gel shift assay, since high concentrations of reductant allow full expression of IRP RNA-binding activity (Hentze *et al.*, 1989). This constitutes a convenient way of checking equal loading of protein on the gel and of expressing RNA binding as percentage of total activity. It should be stressed that maximal binding activity of IRP2 is not visualized at 2% 2-Me but rather at 0.2–0.5% (Bouton *et al.*, 1998). This may explain why, originally, it was sometimes reported that IRP2 was barely sensitive to reductants. Last, the great sensitivity of IRP to reducing agents, especially some cluster-free forms of IRP1 (see later), means that concentrations of reducers like dithiothreitol (DTT) must be kept low in the binding assay buffer.

Figure 3 Representation of the solvent-exposed $[4\text{Fe}-4\text{S}]$ cluster cytosolic IRP1 with citrate bound. Based on the crystal structure of mitochondrial aconitase determined by Robbins and Stout (1989) and adapted from Hirling *et al.* (1994), *EMBO J.* 13, 453–461, by permission of Oxford University Press.

Figure 4 Measurement of IRP activities. IRP1 can display two activities: aconitase activity and IRE binding activity. IRP2 is active only as an IRE-binding protein. In our experiments, aconitase activity was followed spectrophotometrically by the disappearance of *cis*-aconitate at 240 nm. IRE binding activity was measured by an electrophoretic mobility shift assay (EMSA) with excess ^{32}P -labeled IRE probe in the absence and presence of 2% 2-mercaptoethanol which reveals full IRE-binding activity (Hentze *et al.*, 1989). Two IRP-IRE complexes (indicated by the arrows) are resolved in extracts of rodent cells.

Modulation of Iron Regulatory Proteins

A Salient Feature for Posttranslational IRP1 Regulation: A Versatile Fe-S Cluster

Several studies have shown that the entire [Fe-S] center hampers access of the IRE sequence to the residues involved in the RNA-binding domain, and that loss of Fe_a , which induces loss of aconitase activity, is not sufficient to gain IRE-binding capacity (Haile *et al.*, 1992). According to the model proposed by Klausner and Rouault (1993), cluster assembly-disassembly involves the three other iron atoms of the cluster. In the absence of the Fe-S center, the fourth domain of the apo-IRP1 could move away from packed domains 1–3, due to the flexible hinge, to allow an “open” configuration and make the binding site accessible to IREs. Mutation of cysteines 437, 503, and 506 definitively proved the crucial role of the Fe-S center in IRP1 functions. Indeed, IRP1 devoid of Cys-437, or of both Cys-503 and Cys-506, cannot insert the Fe-S center and therefore constitutively binds to IRE sequences (Philpott *et al.*, 1993; Hirling *et al.*, 1994). Accordingly, the form of IRP1 able to bind IRE sequences with a high affinity is thought to be entirely devoid of its Fe-S center (Fig. 5) (Haile *et al.*, 1992; Hirling *et al.*, 1994).

The way IRP1 alternates between the two functions has been widely investigated *in vitro* using sources of iron or iron chelators as well as oxidants and reductants. However, the physiological mechanisms by which IRP1 adapts its structure in response to functional needs are still poorly understood. To understand how IRP1 activities are modulated, it is crucial to elucidate the mechanism whereby [Fe-S] is

assembled in living organisms. *In vitro* experiments show that in solution Fe-S clusters spontaneously assemble in the presence of iron, sulfide, and a reducing agent like DTT. In bacteria, enzymes catalyzing sulfur transfer from cysteine to a Fe-S cluster have been characterized. These sulfur-transferases, originally found to participate in assembly of the Fe-S cluster of *Azotobacter vinelandii* nitrogenase, are termed NifS proteins (Zheng *et al.*, 1993). In yeast, a yeast ortholog (Nfs1p) has been characterized in the mitochondrial matrix (Kispal *et al.*, 1999). Moreover, other data indicate that NifS-like proteins also exist in mammals (Land and Rouault, 1998). It is likely that as yet undefined iron-carrying proteins also participate in Fe-S assembly. Once these putative proteins are fully characterized, it will be interesting to investigate their sensitivity to changes in intracellular iron concentration and to environmental redox messengers.

The Key Role of Cysteine-437

Diamide, a sulfhydryl group blocker, inhibits the *trans*-regulating activity of the apo-IRP1 (Hirling *et al.*, 1994). Apo-IRP1 thus requires free sulfhydryls for its interaction with IRE sequences. Mutation of Cys-437, 503, or 506 to serine showed that only the Cys-437 mutant was fully active in the absence of reductant, whereas IRP1 from cells transfected with Cys-503 or Cys-506 mutant required the presence of low concentrations of 2-Me to be fully active as an RNA-binding protein (Hirling *et al.*, 1994). These experiments confirmed the existence of an oxidized apoprotein form of IRP1. As anticipated by computer prediction based on the structure of mt-aco, the only likely partner to yield a

Figure 5 IRP1: one polypeptide, two functions. Loss of the [4Fe-4S] cluster induces an allosteric switch which causes conversion of the cytosolic aconitase into an IRE-binding protein (Klausner and Rouault, 1993).

disulfide bond between Cys-503 or Cys-506 is Cys-437 (Hirling *et al.*, 1994). In brief, a salient feature to remember is that disulfide bridging between Cys-437 and either Cys-503 or Cys-506 prevents interaction with IRE.

IRP1, a Multifaceted Molecule

The [4Fe-4S] cluster-containing form of IRP1 is active as aconitase, but IRE binding is prevented. In aconitases, 4Fe to 3Fe conversion is accompanied by loss of enzymatic activity. IRP1 obeys the rule, as testified by the *in vitro* experiments of Haile *et al.* (1992) in which a lysate of iron-replete cells was titrated with ferricyanide. At low concentrations of oxidant, aconitase activity was lost, and RNA binding was detectable only in the presence of 2% 2-Me. Substrates that bind 3Fe- as well as 4Fe-clusters prevent activation by 2% 2-Me (Haile *et al.*, 1992). There is evidence that this form also exists in intact cells, as testified by ascorbate induction of a latent aconitase activity in K562 erythroleukemia cells (Toth and Bridges, 1995). This [3Fe-4Fe]⁺-containing form is paramagnetic and emits a typical $g = 2.02$ signal detected by EPR spectroscopy (Basilion *et al.*, 1994; Kennedy *et al.*, 1992).

In vitro experiments showed that at high ferricyanide concentrations ($>100 \mu M$), a cluster-free (apo) IRP1 is formed, as testified by the absence of protection of substrates against 2% 2-Me (Haile *et al.*, 1992). In this conformation, the absence of the 4Fe-4S cluster prevents the bridging between the packed domains 1-3 and domain 4. This relaxed structure can accommodate IRE, but it is worth noting that minute amounts of thiol are necessary to maintain the RNA-binding capability of apo-IRP1 (Haile *et al.*, 1992; Beinert and Kennedy, 1993). In the absence of reducing conditions, this form is biologically inactive.

IRP2, More Than a Spare Wheel

A second protein, first named IRP_B then iron regulatory protein-2 (IRP2), was characterized in rodents and in humans (Henderson *et al.*, 1993; Samaniego *et al.*, 1994; Guo

et al., 1994, 1995). IRP2 cDNA was isolated both in humans and rats, and there is 93% identity between the two species (Guo *et al.*, 1995). IRP2 binds consensus IRE sequences with the same affinity as IRP1 (Kim *et al.*, 1995). IRP2 has a molecular mass of 105 kDa due to an additional 73-amino acid domain near the N-terminal part (Guo *et al.*, 1995; Iwai *et al.*, 1995). Although IRP2 has 16 of the 18 active site amino acids present in IRP1, including cysteines-512, -578, and -581, which are equivalent to those which hold the Fe-S center of IRP1, it does not exhibit aconitase activity. This lack of enzymatic activity is not explained by insertion of the 73-amino acid sequence (Phillips *et al.*, 1996). Moreover, attempts at *in vitro* reconstitution of an Fe-S center in IRP2 were unsuccessful (Phillips *et al.*, 1996). Other studies have focused on the proper role of IRP2 in intracellular iron homeostasis of cells not expressing IRP1 (Schalinske *et al.*, 1997). Other potential peculiar roles include regulation of cellular iron in neurodegenerative disorders (Smith *et al.*, 1998) and c-MYC-dependent control of proliferation/transformation (Wu *et al.*, 1999). Intrinsic role of IRP2 was confirmed by studies with IRP1- and IRP2-deficient mice (T. Rouault, 1999, personal communication).

In contrast to IRP1, IRP2 is degraded in iron-replete cells (Guo *et al.*, 1994; Henderson and Kühn, 1995). This fast degradation depends on the presence of the aforementioned 73-amino acid sequence, which was termed the "iron-dependent degradation domain" (Iwai *et al.*, 1995). Three characteristics deserve attention:

1. The additional sequence contains five cysteines that are potential targets for redox reactions. Mutation of the three cysteines of the CX5CX3C motif to serines abolishes the iron-mediated fast degradation of the protein (Iwai *et al.*, 1995).
2. Degradation was prevented by specific proteasome inhibitors, thus suggesting that IRP2 is degraded by the 26S complex of the proteasome (Iwai *et al.*, 1995; Guo *et al.*, 1995).
3. IRP2 oxidation is a prerequisite for degradation. Many of these oxidized residues, most of which are represented in

the iron-dependent degradation domain, are carbonylated then ubiquitinated prior to degradation by the proteasome (Iwai *et al.*, 1998).

Sensitivity of IRPs to Oxygen and Oxygen Derivatives

It was long believed that activity/expression of IRPs was regulated only by intracellular iron fluxes. However, evidence indicates that physiological redox effectors also play an important part in IRP modulation. As mentioned above, [4Fe–4S] cluster-containing dehydratases, especially aconitases, are susceptible to environmental signals mostly because one of the iron atoms of the [4Fe–4S] cluster lacks a cysteine S-ligand. Even though it is less sensitive to oxygen than its mitochondrial counterpart (Beinert and Kennedy, 1993), IRP1 also reacts to variation in oxygen tension. It was first reported that IRP1 IRE-binding activity of rat hepatoma cells (Hanson and Leibold, 1998) and murine macrophages (Kuriyama-Matsumura *et al.*, 1998) decreased after exposure to hypoxia, probably through stabilization of the 4Fe–4S cluster. In the latter case, the ferritin level was found to be higher than under normoxic conditions. However, data obtained with a human hepatoma cell line were somewhat divergent: on hypoxia, IRE binding was higher, cytosolic aconitase activity was decreased, and ferritin level was reduced (Toth *et al.*, 1999). The effect of oxygen tension on IRP1 might therefore be cell specific.

Alternatively, another explanation can stem from the fact that the electromobility shift assay of IRP RNA-binding capacity does not discriminate between IRP1 and IRP2 in human cells, in contrast to mouse or rat cells. This may explain some discrepancies, because IRP2 expression and activity were later shown to increase under hypoxia in human cells (Hanson *et al.*, 1999). Therefore, hypoxia conversely regulates IRP1 and IRP2 (Hanson and Leibold, 1999). Accordingly, the net result of a change in oxygen tension on ferritin and transferrin expression will likely depend on which IRP predominates with respect to IRE binding. The response of cells to hypoxia provides one of the clues indicating that IRP1 and IRP2 are differentially regulated by environmental messages.

Modulation of IRP1 activities by oxidative stress is outside the main scope of this chapter, but a brief review is apposite. It has long been reported that bacterial [4Fe–4S]²⁺-containing dehydratases including aconitase are very sensitive to oxygen-derived reactive species or hyperbaric conditions (Gardner and Fridovich, 1991; Flint *et al.*, 1993). There are also several data sets indicating that mammalian aconitases are sensitive to superoxide anion (O₂^{•−}) (Hausladen and Fridovich, 1994; Castro *et al.*, 1994). As shown by Gardner *et al.* (1995), endogenously produced O₂^{•−} inactivates mt-aco and cytosolic aconitase–IRP1 in various cell lines. Moreover, aconitases are also inhibited by O₂^{•−} in cell-free systems. Thus, Hausladen and Fridovich (1994) reported that pure mt-aco and cytosolic aco–IRP1 are inactivated by a flux of O₂^{•−} generated by the xanthine–xanthine oxidase

reaction with a constant rate of $\sim 0.8 \times 10^7$ and $\sim 3 \times 10^7$ M^{−1} s^{−1}, respectively. Whereas O₂^{•−} directly inhibits the aconitase activity of IRP1, it does not activate its RNA-binding capacity. Data showed no significant increase in IRE binding of cell lysates in response to the xanthine oxidase-dependent O₂^{•−}-generating system (Bouton *et al.*, 1996) and to paraquat (Pantopoulos *et al.*, 1996). Downregulation was even reported after exposure of pure IRP1 to a flux of O₂^{•−} (Cairo *et al.*, 1996) or treatment of cells by the oxidative stress inducer menadione (Gehring *et al.*, 1999). There is a debate as to whether oxygen-derived oxidants can directly destabilize the IRP1 cluster chemically or whether a more sophisticated signaling pathway is involved (Rouault and Klausner, 1996; Hentze, 1996). A clue may be given by studies showing that phosphorylation of serine-138, which is in the region required for RNA binding, makes the cluster of IRP1 more sensitive to oxidative or nitrosative stress (Brown *et al.*, 1998). In brief, much remains to be clarified if we are to delineate the molecular mechanism sustaining oxidant-dependent cluster disruption. Here we shall just draw attention to some pointers.

There is a consensual view that O₂^{•−} reacts with “cationic” [4Fe–4S] clusters like IRP1’s, but the resulting loss of enzymatic activity is not accompanied by a gain in RNA binding capacity. The most likely explanation is that reaction of O₂^{•−} with IRP1 is limited to the conversion of the 4Fe form to the 3Fe form, which has no biological activity.

Hydrogen peroxide (H₂O₂) does not activate IRP1 binding activity directly (Bouton *et al.*, 1996; Pantopoulos and Hentze, 1995a; Brazzolotto *et al.*, 1999), but it induces a rapid activation of IRE binding capacity in intact cells when applied extracellularly (Martins *et al.*, 1995; Pantopoulos and Hentze, 1995a; Pantopoulos *et al.*, 1997). H₂O₂-dependent activation of IRP1 proceeds through a multistep signaling pathway that is phosphorylation-, temperature- and possibly energy-dependent (Pantopoulos and Hentze, 1998). Activation of IRP1 by H₂O₂ is accompanied by inhibition of ferritin synthesis and by stabilization of transferrin receptor mRNA. IRP2 activity does not seem to be modulated in response to H₂O₂ (Pantopoulos *et al.*, 1996).

NO and the so-called reactive oxygen species are sometimes all tarred with the same brush and are sometimes given the general term of “oxidant” or “perturbant.” Actually, each of these species has its own chemical reactivity, and they likely exert a specific effect on IRP functions.

Modulation of IRP1 by NO

The production of NO from L-arginine was the first biological pathway shown to conversely modulate the two activities of IRP1. This regulation was first observed in activated macrophages and then in other cell types expressing either constitutive or inducible NO synthase (iNOS, NOS-2) (Drapier *et al.*, 1993; Weiss *et al.*, 1993; Jaffrey *et al.*, 1994). It must be stressed that the stimuli that manage induction of NOS-2 in turn control IRP1 functions. γ -Interferon (IFN- γ) and tumor necrosis factor (TNF) upregulate IRE binding

(Drapier *et al.*, 1993; Weiss *et al.*, 1993; Bouton *et al.*, 1998), whereas the two Th2 cytokines interleukin 4 (IL-4) and IL-13 repress it (Weiss *et al.*, 1997). These data establish a connection between the cytokine network (and beyond, i.e., the cell-mediated immunity) and cellular iron homeostasis (Weiss *et al.*, 1995).

Two hypotheses have been advanced for the mechanism by which NO reacts with IRP1. First, NO reacts directly with IRP1, and more precisely its Fe-S center. This assumption was based on three sets of results: (a) the rapidity of the effect of NO both on a cell-free system (Bouton *et al.*, 1996) and on a reporter target cell withdrawn from the NO-generating cell monolayer (Bouton *et al.*, 1998); (b) the prevention of the NO-mediated increase in IRP1 IRE binding on addition of substrates (Bouton *et al.*, 1996); and (c) the appearance of an EPR $g = 2.04$ signal originating from a protein-bound dinitrosyl-iron-dithiol complex on exposure of pure mt-aco and IRP1 to NO (Kennedy *et al.*, 1997). Second, modulation by NO results from reduced intracellular iron pool availability, leading to cellular iron deficiency. In this case, NO would have a delayed and indirect effect on the modulation of IRP1 (Pantopoulos *et al.*, 1996).

NO, Quick or Slow?

One oft-debated question is how fast is NO? This question is central to progress in the understanding of the mechanism by which NO activates the RNA-binding capacity of IRP1. Kinetic arguments argue that NO exerts a slow and indirect effect on IRP1 (Pantopoulos *et al.*, 1996; Hentze and Kühn, 1996). As NO would activate IRP1 as slowly as desferrioxamine-mediated iron depletion, the proposed mechanism involves mobilization of iron by NO which would prevent assembly of the cluster into the neosynthesized IRP1. This hypothesis is supported by the fact that NO yields EPR-detectable complexes with iron within cells (Pellat *et al.*, 1990; Lancaster and Hibbs, 1990). The origin of iron bound to NO in such nitrosyl-iron complexes is ill-defined, but it appears that ferritin, the main iron storage protein, is not involved (P. Lipinski and J.-C. Drapier, 1997, unpublished). One possibility is that NO targets some “transit” and chelatable iron pool, which is believed to be a source of iron available for Fe-S cluster insertion. Two sets of results underpin this hypothesis:

1. IRP1 activation measured in murine primary macrophages, stimulated for endogenous NO production by a combination of IFN- γ and lipopolysaccharide (LPS), increased significantly up to 8 hours and leveled off at 12 hours (Drapier *et al.*, 1993).
2. Rat fibroblasts exposed *in vitro* to chemicals which release NO (“NO donors”) exhibited maximal activity after 8–12 hours (Pantopoulos *et al.*, 1996).

Before interpreting these results, several considerations should be kept in mind. In the first set of experiments, three different measurements were performed in parallel: cytosolic aconitase activity, IRE-binding activity, and NO production

indirectly assessed by nitrite accumulation in culture medium. It is important to remember that NO produced by macrophages is synthesized by NOS-2, which is induced transcriptionally and thus requires time before it is able to produce NO. Care must therefore be taken not to include this delay in the time allotted to NO to activate IRP1. To avoid this bias, we performed coculture experiments by activating adherent macrophages for a steady-state production of NO and then covering macrophages with nonadherent target cells unable to produce NO. These cells were then withdrawn from the macrophage monolayer, and their cytosol was analyzed for IRE-binding capacity. Bouton *et al.* (1998) showed that IRE binding was significantly increased in target cells within 1 hour of contact with NO-producing cells (Fig. 6). We confirmed the rapidity of NO in a cell-free system in which cell lysates were exposed to the mixture 1,3-morpholino-sydnoniminehydrochloride/superoxide dismutase (SIN-1/SOD). Time-course experiments revealed that IRE binding was significantly increased after only 15 min (Bouton *et al.*, 1996; Oliveira *et al.*, 1999). Furthermore, when reduced thioredoxin was added to IRP1 previously exposed to SIN-1/SOD (see below), an increase in RNA binding was detected after only 5 min of exposure to the NO-generating system and was maximal after 30 min (Oliveira *et al.*, 1999).

1) Stimulation of RAW 264.7 macrophages for NO synthesis

2) Co-culture of C58 cells with RAW 264.7 macrophage monolayers

3) Analysis of IRE binding in C58 cells

Figure 6 Rapid upregulation of IRP1 in target cells cocultured with NO-producing cells. Murine RAW 264.7 macrophages were left untreated (control) or stimulated with 10 U/ml IFN- γ and 50 ng/ml LPS for 16 hours. Macrophage monolayers were washed off, and C58 pre-T cells were added in a fresh medium at an effector-to-target ratio of 1 and were analyzed for IRE binding activity by EMSA. Adapted from Bouton *et al.* (1998) with permission.

With regard to the second set of experiments, cells were exposed to exogenous NO released from *S*-nitroso-*N*-acetylpenicillamine (SNAP), or 1-hydroxy-2-oxo-3,3-bis(3-aminoethyl)-1-triazene (NOC-18) also termed DETA-NO. They both triggered RNA binding, but maximal activity was observed after several hours. However, the authors did not provide information about the rate of NO release under their experimental conditions, and this casts doubt on the efficacy of these chemicals at releasing NO quickly. Indeed, NOC-18 is a diazeniumdiolate held to be fairly stable, with a $t_{1/2}$ = 20 hours at 37°C at pH 7.4 (Keefer *et al.*, 1996). SNAP was also successfully used to activate IRP1 in cells in culture (Pantopoulos *et al.*, 1996). SNAP is generally regarded as a fast NO releaser, but as a thionitrite its decomposition rate is highly dependent on the composition of the medium, and release of NO often relies on the presence of trace amounts of copper or iron (McAninly *et al.*, 1993). Therefore, its capacity to release NO may vary from one experiment to another.

Another caveat deserves attention: one of the arguments that supports the supposed slowness of NO is the need to take into account the duration necessary to obtain the maximal RNA binding activity. It may be more relevant to consider the time required to detect the first significant change. Indeed, the switch that allows conversion of the aconitase form (or a null form) to the form that accommodates an IRE is an all-or-nothing mechanism. Accordingly, it seems to us that the time needed for NO to completely achieve the biochemical/structural process which transforms a single molecule of IRP1/aconitase into an IRE-binding protein would be the most relevant parameter to take into account if it were possible to measure it. In brief, if we consider the time corresponding to the start of the rise of RNA binding rather than that of the plateau, NO is unequivocally fast. The lag required to obtain full IRE-binding activity, that is, to have all the molecules of IRP1 able to bind IRE, may be due to suboptimal experimental conditions. Also, it may be physiologically important not to convert every molecule of IRP1 into RNA-binding molecules “in a flash.” A milder effect may be more suitable with respect to cell physiology. It is worth recalling that maximal activity is routinely obtained by adding high concentrations of 2-Me to IRP1. Under these conditions, all forms of IRP1 are converted to RNA-binding forms. There is no reason to assume that a physiological effector like NO has to perform as well. It is probably safe for the cell to keep some of the IRP1 molecules in readiness at least part of the time, especially storage or dormant forms (e.g., the 3 Fe-IRP1) that are rapidly convertible back to aconitase.

Role of Thioredoxin

The notion that a cellular component was probably necessary for an optimal NO-mediated IRP1 activation emerged from the observation that, *in vitro*, activation of IRP1 by NO

was far from maximal. Indeed, when cytosolic extracts are exposed to NO donors, IRP1 activation is consistently lower than that observed in living cells stimulated for NO synthesis. Moreover, treatment of purified recombinant IRP1 with NO donors or with NO gas (Drapier *et al.*, 1993; Bouton *et al.*, 1996) resulted in an even weaker IRP1 activation. In addition, as discussed above, several sets of *in vitro* studies have demonstrated the existence of oxidized IRP1, which, in the absence of a reducing environment, is biologically inactive. Altogether, these observations prompted us to investigate the role of endogenous reducers in the activation of IRP1 mediated by NO, particularly thioredoxin. Thioredoxin is a 12-kDa multifunctional protein that participates in redox reactions through dithiol–disulfide exchange reactions. Oxidized thioredoxin is reduced by NADPH and thioredoxin reductase. In its reduced form, thioredoxin has been implicated in the regulation of the DNA binding activity of several redox-sensitive transcription factors including NF- κ B, activator protein 1 (AP-1) via reduction of Ref-1, glucocorticoid receptor, and heat shock factor-1 (Holmgren, 1985; Nakamura *et al.*, 1997).

Oliveira *et al.* (1999) showed that reduced thioredoxin strongly potentiated the IRE-binding activity of IRP1 in cytosolic extracts that had been concentrated on a membrane with an M_r cutoff of 30,000 and exposed to NO (Fig. 7). Optimal IRP1–IRE binding activity could also be observed by exposing NO-treated recombinant IRP1 to the thioredoxin system. Furthermore, we demonstrated that neutralization of endogenous thioredoxin with an anti-thioredoxin monoclonal antibody abolished the increase in RNA-binding activity of IRP1 in cytosolic extracts exposed to NO. These results point to endogenous thioredoxin as a cellular companion of NO in accelerating IRP1–IRE binding.

Modulation of IRP2 by NO

Whether or not IRP2 is modulated by NO and with what consequences is still controversial. The IRE-binding activity of IRP2 was increased in a B6 fibroblast cell line transfected to overexpress NOS-2 mRNA (Pantopoulos and Hentze, 1995b). On the other hand, in a rat hepatoma cell line, neither induction of NOS-2 by cytokines nor exposure of the cells to NO donors modulated IRP2 activity or expression (Phillips *et al.*, 1996). Moreover, two independent studies reported that expression of *trans*-regulating activity of IRP2 was decreased in macrophages stimulated *in vitro* by the combination of IFN- γ and LPS. In one case the authors claimed that the downregulation observed was mediated by NO synthesis (Recalcati *et al.*, 1998), whereas in the other case the authors concluded that it was not (Bouton *et al.*, 1998). However, the main point is that IRP2 is regulated differently than IRP1 in murine macrophages activated by IFN- γ and LPS. In brief, if IRP2 is regulated differently or even oppositely to IRP1, it could help balance IRP1-mediated control of iron metabolism.

Figure 7 Cooperation between NO and thioredoxin in activating IRP1. Cytosolic extracts from RAW 264.7 cells were exposed to 5 mM SIN-1 in the presence of 3000 U/ml superoxide dismutase for the time indicated. After filtration on a P-6 Bio-Spin column, extracts were incubated with 5 μ M thioredoxin (TRX), 1 nM thioredoxin reductase, and 0.4 mM NADPH for 20 min prior to analysis by EMSA in the presence and absence of 2% 2-mercaptoethanol. Adapted from Oliveira *et al.* (1999) with permission.

Physiological Consequences of NO-Dependent Modulation of IRPs

Because IRP binding to IRE results in repression of ferritin translation and transferrin receptor mRNA stability, NO synthesis, by activating IRP1, was expected to decrease ferritin expression and increase transferrin receptor synthesis. Several lines of evidence indicate that ferritin translation is repressed in response to NO-mediated activation of IRP1. As shown by Weiss *et al.* (1993), ferritin H- and L-chains were downregulated in the J774 macrophage cell line stimulated for NO synthesis, whereas the ferritin mRNA level was unchanged. Furthermore, the same authors confirmed the regulation of ferritin translation by NO using a fibroblast cell line stably transformed to constitutively express NOS-2 (Pantopoulos and Hentze, 1995b). However, not all data agree with a NO-mediated reduction in ferritin expression. Indeed, exposure of K562 erythroleukemia cells to the NO-generator SNAP had no effect on the intracellular ferritin level, despite IRP1 activation (Oria *et al.*, 1995). Moreover, as reported by Recalcati *et al.* (1998), stimulation of J774 cells by cytokines and LPS induced an increase in ferritin synthesis. These conflicting results may be explained by the intrinsic, and at times predominant, role of IRP2, which, as mentioned above, is often regulated in an opposite way to IRP1.

At first glance, the situation regarding NO modulation of the IRP-IRE system and transferrin receptor expression is also somewhat puzzling. Cairo and Pietrangelo (1995) showed that during experimental inflammation, transferrin receptor mRNA content was increased in response to enhancement of NOS-2 expression. In several independent *in vitro* studies, it was shown that treatment of cells by SNAP increases IRP1 activity and transferrin receptor expression (Pantopoulos and Hentze, 1995b; Oria *et al.*, 1995; Richardson *et al.*, 1995). Moreover, in two of these studies, it was reported that sodium nitroprussiate, which releases an NO⁺-like molecule, had no effect or even downregulated both

IRP1 activity and transferrin receptor expression (Richardson *et al.*, 1995). Mechanistically, it makes sense that molecules with an NO⁺ character are more efficient at reacting with thiolate than with iron. Actually, as long as the critical cysteines of IRP1 (Cys-437, Cys-503, and Cys-506) are bound to (and therefore shielded by) the Fe-S cluster, the compact structure of IRP1 is hardly reachable by IRE. Thus, depending on the redox environment, NO release may have different consequences for IRP1 activity and, in turn, for transferrin receptor expression.

As pointed out by two groups, stimulation of cells by IFN- γ and LPS lowers transferrin receptor mRNA levels, whether NO is produced or not (Phillips *et al.*, 1996; Pantopoulos and Hentze, 1995b). As cells transformed to overexpress NOS-2 exhibit a severalfold increase in transferrin receptor mRNA mediated by the IRP-IRE interaction (Pantopoulos and Hentze, 1995b), it was proposed that downregulation of transferrin receptor expression in response to IFN- γ and/or LPS exceeds the positive effect of NO. It is possible that despite activation of IRP1 (via NO), IFN- γ /LPS-mediated downregulation of IRP2 governs posttranscriptional regulation of transferrin receptor.

Regulation by Peroxynitrite

It is believed that peroxynitrite attacks the Fe-S clusters (Keyer and Imlay, 1997), and it was not surprising that IRP1 became a likely member of the fast-growing list of its targets. Hausladen and Fridovich (1994) first studied the effect of peroxynitrite on IRP1, and they reported inactivation of aconitase activity of pure IRP1 by bolus addition of peroxynitrite. The experiment was performed under special *in vitro* conditions (i.e., pH 9) in which peroxynitrite is relatively (and unphysiologically) stable. However, RNA-binding activity was not tested. Inactivation of mt-aco or cyt-aco/IRP1 by peroxynitrite was reported by other groups (Castro *et al.*,

1994; Bouton *et al.*, 1997; Kennedy *et al.*, 1997). There is a consensus view that exposure of aconitases (as crude preparation or pure) to bolus addition of peroxynitrite leads to loss of activity even though the efficacy of peroxynitrite is assessed differently. Indeed, as reported by Castro *et al.* (1994) peroxynitrite has a strong affinity for mt-aco ($k = 1.4 \times 10^{-5} M^{-1}s^{-1}$). On the other hand, Kennedy *et al.* (1997) noted a relative resistance of both mt-aco and cytosolic aconitase/IRP1 to peroxynitrite.

With regard to the IRE-binding capacity of IRP1 on exposure of peroxynitrite, the situation was far from explicit. Whereas treatment of cells or cell lysates with NO donors (SNAP, NONOates, SIN1 plus SOD) increased IRE-binding activity of IRP1, treatments that produce peroxynitrite formation (SIN-1 alone, SNAP plus paraquat) did not (Bouton *et al.*, 1996; Pantopoulos and Hentze, 1995a; Richardson *et al.*, 1995). Radi and co-workers analyzed the effect of NO and peroxynitrite on the activity of mt-aco and on both aconitase and RNA-binding activities of IRP1 in intact fibroblasts. When intact cells were exposed to exogenous NO released from a diazeniumdiolate, hydroxy-2-oxo-3-(*N*-ethyl-3-aminoethyl)-3-ethyl-1-triazene (NOC-12), they exhibited lower aconitase activity and higher IRE-binding activity. The latter activity was significantly increased after a 30-min exposure to 1 μM /min NO and reached 100% after 4 hours. In the same set of experiments, peroxynitrite, either applied to cells as a bolus or endogenously produced by cells both exposed to NOC-12 and treated with antimycin A, also triggered an increase in RNA binding (Castro *et al.*, 1998).

Before addressing the question of whether (and how) such a powerful oxidant as peroxynitrite could modulate IRP1, it is worth recalling some important indicators. As mentioned above, for IRP1, one function precludes the other. This postulate wrongly led to the deduction that loss of aconitase activity of peroxynitrite-exposed IRP1 necessarily conferred a gain in RNA-binding activity. In fact, one of the clues to comprehending this issue is to realize that the “one polypeptide, two mutually exclusive functions” concept, as regards IRP1, is probably rather simplistic. Indeed at least *in vitro*, two other forms can also exist: a 3Fe-containing form and an oxidized “apo” form. None of these forms has any biological activity, and therefore they are barely detectable. Hence four forms can interconvert, of which only the two canonical forms, that is, the aconitase and the IRE binding protein, are generally detected. The two “null” forms may be used as storage proteins, which are rapidly convertible to biologically active forms (Toth and Bridges, 1995; Drapier and Bouton, 1996).

Another basic clue in delineating the role of redox active species like peroxynitrite on IRP1 is to admit that IRP1 binds IRE on reduction. This assumption, it is very important to recall, has been documented by many reports. Early studies determined that exposure of IRP1 to 2% 2-Me fully activated its IRE-binding activity (Hentze *et al.*, 1989). Above all, a series of careful studies showed that in cluster-free IRP1, Cys-437 is a reactive residue whose redox status is crucial for IRE binding (Philpott *et al.*, 1993; Hirling *et al.*, 1994).

As mentioned previously, Hirling *et al.* (1994) provided evidence that Cys-503 in IRP1 lacking Cys-506 and Cys-506 in IRP1 lacking Cys-503 are linked to another cysteine by a disulfide bond, and they concluded that the Cys-437 was the only partner for the remaining cysteine. In short, it is important to draw attention to the fact that removal of the cluster from IRP1 is necessary but not sufficient to achieve RNA binding. A reducing environment is also crucial to prevent Cys-437 from forming a bridge with Cys-503 or Cys-506.

Taken together, these considerations led us to evaluate the effect of peroxynitrite on IRP1 IRE binding. We confirmed that peroxynitrite inhibits the enzymatic activity of IRP1 without degrading the protein. However, IRP1 did not gain RNA-binding activity (Bouton *et al.*, 1997). To solve this somewhat mystifying question, the mechanism of action of peroxynitrite on IRP1 was further studied *in vitro* by exposing IRP1 previously treated with peroxynitrite to suboptimal concentrations of 2-Me. It was thus concluded that not only does peroxynitrite disrupt the Fe-S center of IRP1, but it also promotes formation of an oxidized apo-IRP1 exhibiting neither aconitase activity nor *trans*-regulatory activity. Furthermore, site-directed mutagenesis showed that peroxynitrite allows formation of a disulfide bridge involving Cys-437 (Bouton *et al.*, 1997). In such an oxidized form, IRP1 has no biological activity. It was concluded that peroxynitrite may predispose IRP1 to bind IRE sequences only if the protein is then placed in a very slightly reducing environment. Such a narrow dependence on reducing systems may explain some paradoxical results reported in the literature.

It is known that IRP2 activity is lost on exposure to diamide or 5,5-dithiobis(2-nitrobenzoic acid), but can be recovered in the presence of 2-Me or DTT (Phillips *et al.*, 1996; Henderson and Kühn, 1995). The effect of peroxynitrite on its RNA-binding activity was studied by Bouton *et al.* (1997). RNA-binding capacity was lost in response to peroxynitrite, but the protein was not degraded, as shown by recovery of full activity in the presence of 2-Me. Thus, IRP2 can also be modulated posttranslationally in response to redox influence.

Aconitase Inhibition: The Respective Roles of NO and Peroxynitrite

The debate concerning modulation of aconitase and IRP1 activities relates to whether NO or one of its higher oxides inhibits enzymatic activity of aconitases in general and more specifically that of IRP1. Let us first consider the data.

In the mid 1980s, mt-aco activity loss was noted in cells activated to synthesize NO or in cells adjacent to NO-producing cells (Drapier and Hibbs, 1986, 1988). Ten years later, several independent studies showed that cells stimulated to produce NO or cytosolic extracts exposed to NO donors exhibited increased RNA-binding capacity and loss of cytosolic aconitase activity (Drapier *et al.*, 1993; Weiss *et al.*, 1993; Bouton *et al.*, 1996). In one of these reports, it was stated that pure NO gas diluted in buffer could inhibit the aconitase activity of purified recombinant IRP1 and increase

its RNA binding activity, thus pointing to a direct effect of NO (Drapier *et al.*, 1993). Two groups compared the effect of NO and peroxynitrite on aconitases *in vitro*. Castro *et al.* (1994) found that NO under anaerobic conditions moderately inhibited commercial porcine mitochondrial aconitase, whereas Hausladen and Fridovich (1994) did not find any effect of NO on either mt-aco or purified cytosolic aconitase/IRP1 enzymatic activity. Consequently, both groups concluded that peroxynitrite rather than NO was the molecule responsible for aconitase inhibition on NOS activation.

The issue was then addressed by Kennedy *et al.* (1997). They found that NO, either applied anaerobically as a buffered solution of NO gas or aerobically released from a precursor, was able to inactivate both mitochondrial and cytosolic aconitase/IRP1. Inactivation of both aconitases was accompanied by the formation of an EPR-detectable signal typical of dinitrosyl-iron-thiol complexes.

More recently, Gardner *et al.* (1997) reinvestigated the issue by exposing bacterial culture or mammalian mt-aco to a solution of NO gas. They found that moderate amounts of NO (120 ppm) applied to *Escherichia coli* culture under anaerobic conditions were sufficient to cause ~70% loss of aconitase activity in 2 hours. Furthermore, by using MnSOD-overexpressing or glutathione-deficient *E. coli* mutant strains, they determined that neither O₂⁻ nor peroxynitrite was necessary in NO-mediated inhibition of aconitase. In *in vitro* experiments under various conditions (pH, salts, etc.), they noted that enhancing ionic strength or the presence of *cis*-aconitate increased inhibition. Above all, they also reported that lowering pH favors inhibition. This feature may reconcile most, if not all, of the discrepancies mentioned above. Indeed, in Gardner's experiments, mt-aco exposed to NO at pH 7.5 was fairly resistant to inactivation, which is consistent with the data of Castro *et al.* (1994) and of Hausladen and Fridovich (1994) with mt-aco. However, when the experiments were performed at pH 6.5–6.8, activity was inhibited. In brief, according to Gardner *et al.* (1997), a few tenths of a pH unit are crucial to determine resistance or sensitivity of mt-aco to NO *in vitro*. This observation may likely be extrapolated to IRP1. Indeed, it is striking that the experiments of Kennedy *et al.* (1997) demonstrating inhibition of mammalian mt-aco and cytosolic aconitase/IRP1 by spermine-NONOate (sper-NO) were also conducted at pH 6.6. The prolonged debate about the sensitivity of aconitases to NO may therefore simply be solved by careful examination and control of the buffering conditions. This precaution would be particularly suitable when NO is added to protein under not strictly anaerobic conditions, because NO and oxygen in aqueous solution can yield nitrous acid which may lower the pH of buffers.

Taken together, these data indicate that exposure of *intact* bacteria or mammalian cells to NO applied as gas in buffered solution or released from NO synthase or chemicals, *does* lead to aconitase inhibition (Drapier and Hibbs, 1996; Gardner *et al.*, 1997; Castro *et al.*, 1998). At this juncture, it is important to bear in mind that under such experimental conditions (which approximate the physiological situation), the

efficacy of NO has not been contested. The situation is more debatable with regard to the *in vitro* experiments. Gardner's data provided a valuable clue to better understanding of the issue by revealing the sharp pH dependence of NO in its inhibition of aconitases (Gardner *et al.*, 1997). Yet the molecular mechanism explaining why aconitases would be more sensitive to NO at slightly acidic pH and possibly in the presence of *cis*-aconitate is still a matter of speculation. It has been proposed that a change of active site conformation following ionization of the side chains of the active site amino acid or an alteration of the ligand field of Fe_a may affect NO reactivity (Gardner *et al.*, 1997).

Concluding Remarks

In the NO versus IRP play, the cast is auspicious for at least two reasons: (1) physiologically, NO, at least produced by the cytokine-induced NOS-2, can opportunely appear and ambush at the juncture between innate immunity and cellular iron metabolism, and (2) biochemically, NO is a reactive messenger that faces two very receptive proteins. IRP1 possesses a watchful Fe-S cluster that senses and sorts the chemical signals. Several lines of evidence indicate that NO quickly reacts with IRP1. As expected from the Lewis acid character of Fe_a, NO probably interacts with the Fe-S cluster. Indeed, it leaves a footprint, that is, an EPR-detectable nitrosyl-iron complex. Yet, to complete binding to IRE sequences, it relies on an endogenous reducing system. Thioredoxin is a likely partner in this regard. Peroxynitrite is fast at inactivating the aconitase activity of IRP1, but, as a potent oxidant, it would hardly activate IRE binding because it oxidizes Cys-437.

Peroxynitrite-exposed IRP1 would accommodate IRE in the situation where a reducing system (thioredoxin again?) would intervene once peroxynitrite has vanished. IRP2 is also sensitive to oxidoreduction. It has no Fe-S cluster, but several cysteines are likely to be S-nitrosylated or oxidized. Consequently, dissecting the mechanisms that underlie the modifications of IRPs by NO and accomplices such as peroxynitrite is a worthwhile objective in striving to improve knowledge of the actions of NO.

Nitric Oxide, Oxidative Stress, and Signal Transduction

Martine Torres* and Henry Jay Forman†

**Childrens Hospital Los Angeles Research Institute, Department of Pediatrics, School of Medicine,*

*†Department of Molecular Pharmacology and Toxicology, School of Pharmacy,
University of Southern California, Los Angeles, California*

WHEREAS THE PARTICIPATION OF NITRIC OXIDE (NO), A FREE RADICAL, IN SIGNAL TRANSDUCTION IS WELL ESTABLISHED, THE ROLES OF SUPEROXIDE (O_2^-), HYDROGEN PEROXIDE (H_2O_2), AND PEROXYNITRITE ($ONOO^-$) ARE LESS WELL UNDERSTOOD. THIS CHAPTER DESCRIBES THE PROPERTIES OF SECOND MESSENGERS AND HOW THESE OXIDANTS FIT INTO THIS ESSENTIAL ROLE IN SIGNAL TRANSDUCTION. AN IMPORTANT ASPECT OF THIS DISCUSSION IS THE CAVEATS THAT MUST BE CONSIDERED, INCLUDING AN EXAMINATION OF THE USE OF ANTIOXIDANTS. THE EVIDENCE FOR INVOLVEMENT OF OXIDANTS IN SIGNALING IS SUBSTANTIAL, AND THIS CHAPTER DESCRIBES THE VARIOUS SIGNALING PATHWAYS TRIGGERED BY OXIDANTS. TRANSIENT CHANGES IN INTRACELLULAR FREE CALCIUM CONCENTRATION, ACTIVATION OF PHOSPHOLIPASES, AND MODULATION OF PROTEIN KINASE C (PKC), THE MITOGEN-ACTIVATED PROTEIN KINASES, AND PROTEIN TYROSINE PHOSPHATASES ARE EXAMINED. BOTH THE ESSENTIAL ELEMENTS IN THE SIGNALING PATHWAYS AND THE SITE WHERE OXIDANTS MAY ACT ARE DESCRIBED. THE MAJOR ROLE OF PROTEIN CYSTEINE RESIDUES AS SITES FOR INTERACTION WITH OXIDANTS IN TRANSMISSION OF SIGNALING IS EXAMINED. FINALLY, THE TRANSCRIPTION FACTORS AND *CIS*-ACTING ELEMENTS THAT RESPOND TO OXIDANT-INDUCED SIGNALING OF GENE EXPRESSION ARE BRIEFLY EXAMINED. THE PICTURE THAT EMERGES IS SOMEWHAT FUZZY BUT IS BECOMING INCREASINGLY CLEAR.

General Introduction

Free radicals and related oxidizing species, such as hydrogen peroxide (H_2O_2) and peroxynitrite ($ONOO^-$), were long considered to be agents of cell and tissue damage only through random oxidation of tissue components. Even where these reactive species had been demonstrated to have a beneficial role in biology, such as in the microbicidal action of phagocytes, their action was ultimately destructive. This chapter describes some of the chemistry involved in the destructive aspect of oxidative stress; however, the main focus is on the role of reactive oxygen and nitrogen species in signal transduction.

A Brief Review of Reactive Oxygen and Nitrogen Biochemistry

Before the role of reactive oxygen and nitrogen species in signaling pathways can be discussed, it is important to understand how these molecules are generated in cells, some of their chemical properties, and the nonenzymatic reactions that produce cellular damage. More than 95% of the O_2 consumption of tissues is the result of its reduction to H_2O by cytochrome oxidase in mitochondria, a reaction that does not release any intermediates. The remaining consumption of O_2 involves univalent and divalent reduction in which the reactive oxygen species superoxide anion radical (O_2^-) and hydrogen peroxide are produced, respectively:

The univalent reduction of O_2 [reaction (1)] results in the formation of O_2^- and occurs under various conditions: the respiratory burst NAD(P)H oxidase in phagocytes and related oxidases (see later); leak of electrons from the mitochondrial electron transport chain, which is most likely due to autooxidation of ubiquinone and is probably the largest source of superoxide generation in nonphagocytosing cells; reactions of some monooxygenases; reactions catalyzed by dehydrogenases (when “leaking” electrons to oxygen); and metal-catalyzed autooxidation of small molecules and oxyhemoglobin. Superoxide is both a reducing and oxidizing agent but is not a particularly reactive species with organic compounds; however, it does react with iron–sulfur centers, such as in aconitase, which it inactivates. At acidic pH, superoxide is protonated to form hydroperoxyl (HO_2^\bullet), and it is more reactive with membrane lipids because of its greater lipophilicity and reactivity. Most of the “danger” from superoxide appears to come from species derived from it.

The divalent reduction of oxygen yields the nonradical species hydrogen peroxide [reaction (2)]. Sources of hydrogen peroxide that catalyze such divalent reduction are monooxygenases, namely, glucose oxidase or D-amino acid oxidase. Some monooxygenases release both superoxide and hydrogen peroxide. Another major source of hydrogen peroxide is the dismutation of superoxide:

Dismutation occurs nonenzymatically and is rapid ($\sim 10^5 \text{ mol}^{-1} \text{ s}^{-1}$) at physiological pH, but it is markedly accelerated by the superoxide dismutases ($>10^9 \text{ mol}^{-1} \text{ s}^{-1}$). Hydrogen peroxide is fully protonated at physiological pH, has a relatively long half-life, is membrane permeable, and may cause damage at sites distant from its origin. Iron bound to proteins may be reduced by superoxide, which may simultaneously cause release of the metal, enhancing its reactivity [reaction (4a)]. In the presence of reduced transition metals, such as iron and copper, hydrogen peroxide is reduced to hydroxyl radical ($\cdot\text{OH}$) and hydroxyl ion (OH^-), a reaction referred to as the Haber–Weiss reaction or the superoxide-driven Fenton reaction [reaction (4b)]:

Hydroxyl radical is extremely reactive and will react with any organic molecule, with the rate of reaction near diffusion limitation. Therefore, it modifies molecules immediately adjacent to its site of generation, usually by hydrogen abstraction. This can result in a chain reaction, such as lipid peroxidation:

where LH is an unsaturated fatty acid.

Much of the toxicity of superoxide may be mediated through its reaction with nitric oxide (nitrogen monoxide, NO), the main subject of this book, the chemistry of which is covered far more extensively in other chapters. Peroxynitrite (ONOO^-) is formed very rapidly ($6.7 \times 10^9 \text{ mol}^{-1} \text{ s}^{-1}$) [reaction (8)]:

Like superoxide, peroxynitrite is not a particularly reactive species, whereas the protonated form, peroxynitrous acid, is unstable and has the potential to react with organic molecules with chemistry similar to both nitrogen dioxide (NO_2^\bullet) and hydroxyl radical. Activated macrophages, which can produce both superoxide and nitric oxide, can use peroxynitrite formation to destroy harmful organisms, and reaction (8) may play a role in chronic inflammation and tissue injury as well. The physiological actions of nitric oxide in vasodilation and neurotransmission are well established and are among the clearest examples of a role for free radicals in normal physiology. These physiological effects are largely mediated through the activation of guanylate cyclase by nitric oxide. The formation of and signaling by nitric oxide are extensively described in other chapters. Thus, here we will only address the potential participation of peroxynitrite in oxidative signaling.

General Concepts of Signal Transduction

Signal transduction is a regulated sequence of biochemical steps through which a stimulant conveys a message resulting in a physiological response. The key words here are “regulated” and “biochemical steps.” In signal transduction, regulation usually involves transient changes in the steady-state concentrations of metabolites or ions and phosphorylation of proteins. With few exceptions, most of these changes involve the rapid “turning on” and then “turning off” of enzymatic or ion channel activities. This, however, does not require the process to be a reversible reaction, as the return to the previous state can be through a different pathway. Examples of this rapid cycling are seen in the free intracellular calcium ion concentration, which increases severalfold for a few seconds to minutes, the phosphorylation of protein kinases that are then dephosphorylated, and the transient 10-fold elevation in the concentration of cyclic AMP (cAMP) that lasts less than a minute. The duration and extent of such changes vary with stimulant and cell type. The biochemical steps involved in signal transduction are mostly enzyme-catalyzed reactions that are regulated by either allosteric modulation due to binding of small molecules (second messengers, such as cAMP) or to reversible phosphorylation.

Signal transduction cascades begin with the binding of an agonist (stimulant) to its receptor protein. The largest class of receptors are the cell surface transmembrane proteins, with binding domains for the agonist on the outside of the cell and transducing domains on the inside. Nonetheless, there are numerous receptors also found in the cytosol (i.e.,

steroid hormone receptors) and on other membranes [i.e., the inositol-1,3,4-trisphosphate (IP_3) receptor on the endoplasmic reticulum]. Figure 1 shows the general scheme for signaling through a type of membrane receptor that is coupled to heterotrimeric G proteins. Figure 2 shows a more detailed scheme for the activation of Ca^{2+} -dependent signaling.

Figures 1 and 2 show only the steps involved in the initiation of signaling that result in a change in cell function but not the steps that result in ending or reversing these changes. For signaling through heterotrimeric G proteins, this occurs when the $G\alpha$ subunit, which is a GTPase, hydrolyzes GTP to GDP and inorganic phosphate and then dissociates from the effector. Many receptors have been found to be inactivated by phosphorylation, catalyzed by one of the protein kinases activated through that receptor. To stop signaling at other steps, second messengers are decreased in concentration. For an ion such as Ca^{2+} , this occurs through activation of calcium-ATPases that move the ion into storage (endoplasmic reticulum or sarcoplasmic reticulum in muscle) or out of the cell. For second messengers such as cAMP, the concentration is lowered by enzymatic degradation. The decreases in second messengers cause dissociation and inactivation of effectors. Dephosphorylation by a protein phosphatase can decrease the activity of an effector that was activated by a protein kinase. Some effectors, however, may be initially activated by removal of phosphate and then inactivated by phosphorylation. Once the initial processes are reversed, the cell can return to its prestimulation state.

Reactive Oxygen and Nitrogen Species as Second Messengers: Characteristics

Second messengers have four basic characteristics that allow regulation. (1) They are either enzymatically gener-

ated or regulated by channels and pumps. (2) They are enzymatically degraded. (3) Their concentration rises and falls within a short period. (4) They are specific in action.

How do the reactive oxygen and nitrogen species fit into signaling? Superoxide and hydrogen peroxide have all four of the characteristics of second messengers just defined. They are generated enzymatically as described above, degraded by superoxide dismutases or catalase and glutathione peroxidases, are present at very low concentrations but can transiently be elevated to measurable amounts, and do not react randomly.

Peroxynitrite is not made in the active site of an enzyme but depends on the generation of superoxide and nitric oxide, which is regulated. Therefore, as the reaction that produces peroxynitrite is diffusion limited, its generation is as enzymatically regulated as are its precursors. Peroxynitrite is not itself highly reactive; however, its acid form, peroxynitrous acid, is very unstable and reactive. S-Nitrosation, that is, the formation of S-nitrosothiols by reaction of peroxynitrite with the cysteine residues of proteins or glutathione, provides a source of bioavailable nitric oxide, but it has also been proposed to regulate the activity of enzymes, thereby representing a possible signaling mechanism. Peroxynitrite also irreversibly modifies tyrosine residues, producing nitrotyrosines. The process of tyrosine nitration may also play a role in signaling by altering the activity of critical enzymes through covalent dimerization, as shown with the EGF receptor. Tyrosine nitration of proteins occurs in neutrophils treated with peroxynitrite, resulting in priming of the NADPH oxidase. These effects are observed with exogenous peroxynitrite over a large range of concentrations; whether endogenous peroxynitrite production produces similar effects is still a matter of debate. Peroxynitrite may participate in signaling processes at low concentrations but, at greater concentrations, it will produce toxicity (presumably through

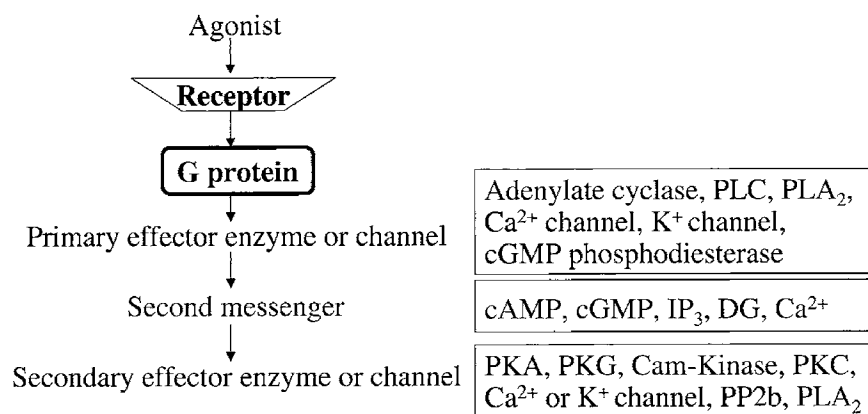

Figure 1 General scheme for heterotrimeric G protein coupled receptor signaling. An agonist binds to a specific receptor and changes its conformation. This signals two changes in the heterotrimeric G proteins. Initially, GDP is bound to the $G\alpha$ subunit of the heterotrimer. GDP dissociates from $G\alpha$ when GTP binds to this protein. The GTP-bound $G\alpha$ then dissociates from the $G\beta\gamma$ subunits. The GTP-bound $G\alpha$ and/or the $G\beta\gamma$ dimer then binds to another protein called an effector. This effector may be a channel that opens, allowing ion flow, or it may be an enzyme that is activated as long as the G protein is bound to it. The effector enzyme produces a small molecule that acts as a second messenger. This second messenger then binds to another effector, causing a conformational change that activates its activity.

Figure 2 Calcium-dependent signaling. A heterotrimeric G protein coupled receptor (GPCR) activates G α_q (a subtype of the G α class), which binds to and activates phospholipase C β (PLC β). This enzyme then cleaves phosphatidylinositol 4,5-bisphosphate (PIP₂) to form two second messengers, inositol-1,4,5-trisphosphate (IP₃) and diacylglycerol (DAG). IP₃ binds to a receptor channel on the endoplasmic reticulum, which opens and allows Ca²⁺ to flow down a concentration gradient into the cytosol. The increase in cytosolic Ca²⁺ concentration activates Ca²⁺-dependent enzymes, such as the α , β , and γ isoforms of protein kinase C (PKC), and binds to a protein called calmodulin, allowing it to activate enzymes such as calmodulin-dependent kinase (CamK) and the calmodulin-dependent protein phosphatase (PP2b or calcineurin). DAG also is necessary for activation of several protein kinase C isoforms.

formation of peroxynitrous acid or metal-catalyzed reaction). The fate of nitric oxide, namely, conversion to nitrite and nitrate, is well established. Peroxynitrite can isomerize to nitrate or decompose to form nitrite. Nonetheless, there is no known enzymatic pathway for degradation of peroxynitrite or nitric oxide.

Hydroxyl radical formation depends on random encounters between hydrogen peroxide and reduced transition metals. Hydroxyl radical is so reactive that it has no chance for specific action because it reacts with almost every organic molecule at nearly the same rate. Instead, hydroxyl radical is responsible for causing random damage to cellular constituents, including DNA. If the damage is not lethal, DNA repair systems are signaled, but this is actually a response to injury rather than a specific response to hydroxyl radical. Obviously, this free radical does not fit the criteria for a second messenger.

Evidence for Participation of Oxidants in Signaling

Because of their chemical reactivity, giving oxidants the ability to randomly oxidize cellular constituents, it is easy to conceive how oxidants could interfere with signaling or any other cellular function. The preceding discussion suggests that some oxidants have characteristics of second messengers; however, the evidence that they function as such is not

yet as clear, in part due to difficulties in ascertaining their production and site of action. The following section discusses some of the caveats associated with this rapidly developing area of investigation.

One of the major problems is that the analytical tools used for measuring the generation of oxidants in cells either are not sensitive to transient fluctuations in radical concentrations (spin trapping) or are not specific for a particular oxidant. A second difficulty in identifying how oxidants act in signaling is to determine the effectors that recognize these reactive species in a specific and reversible manner. This makes establishing quantitative and temporal relationships between oxidant production and signaling quite difficult. This has not been addressed rigorously for many of the pathways. A third problem is that the majority of the studies have relied on the addition of exogenous oxidants to the cells to demonstrate their effects on cell function. Fortunately, there has been a marked decline in the use of “thermonuclear” concentrations of oxidants in studying the effects; however, the literature has many examples of studies where cells have been “bleached” rather than gently provoked. Although the prudent use of physiologically relevant concentrations of exogenous oxidants is valuable, the results must be carefully considered and interpreted to reach proper conclusions. Finally, a problem inherent to all signal transduction studies is the use of purportedly specific inhibitors, which can result in

misinterpretation. In this context, molecules with antioxidant properties are often used to implicate oxidants in a particular pathway. The rationale is that a reductant will act as an inhibitor of signaling by reacting with the oxidant (commonly called scavenging). Thus, using these molecules allows the demonstration of a possible correlation between diminished oxidant steady-state concentration and diminished signaling, such as activity of a protein kinase. Unfortunately, antioxidants are not particularly specific in their action, and many of the commonly used agents are not actually directly reactive with oxidants under physiological conditions. For example, *N*-acetylcysteine (NAC), which is widely used as an antioxidant, does not readily react with superoxide or hydrogen peroxide. Rather, this thiol compound can react with protein disulfides as does GSH [see reaction (13)] or act as a precursor for cysteine, which is needed for GSH synthesis. In this manner, NAC may appear to inhibit oxidant-induced signaling via an indirect mechanism. On the other hand, NAC added to the outside of cells may reduce disulfides that are necessary for the function of surface receptors and channels. NAC can also reduce transition metals and thereby promote the production of reactive oxygen species and Fenton chemistry [see reaction (4b)] as well as give rise to a thiyl radical that can initiate other oxidative chemistry:

Although commonly used to indicate the potential involvement of oxidants in signaling, NAC can initiate signaling through its prooxidant chemistry. Another thiol compound, pyrrolidine dithiocarbamate (PDTC), also does not react rapidly with superoxide or hydrogen peroxide but reacts with transition metals. Actually, PDTC is an excellent chelator of copper, and its ability to interfere in signal transduction has been shown to be due to a prooxidant rather than antioxidant reaction, although still used as such. Even antioxidants such as vitamin E that can clearly inhibit lipid peroxidation may have other effects, such as activation of a protein phosphatase that affects signaling by a nonredox mechanism. Another type of reagent, the so-called hydroxyl radical scavenger (DMSO, mannitol, etc.), has been used extensively to inhibit oxidative signaling and to implicate hydroxyl radicals in these processes. Knowing the extreme reactivity of hydroxyl radicals, it is hard to conceive how any compound could have an advantage as a hydroxyl radical scavenger over hundreds of other compounds already present in any biological system, as all organic compounds react with hydroxyl radical with rate constants approaching diffusion limitation. Thus, in solution, for any "scavenger" to be 50% effective, it would have to be present at equal or greater concentration than all of those other compounds. The argument might be made that some compound binds to a specific target of oxidation and prevents its oxidation due to Fenton-like chemistry; however, the case must be made then for specificity of binding to that particular site. Thus, the use of antioxidants as tools in studying signal transduction is useful as long as the results are interpreted as poten-

tially indicative of oxidant signaling rather than definitive evidence.

Where Do Oxidants Act to Initiate Signaling?

Oxidation of a critically placed protein cysteine residue appears to be the major chemical alteration caused by oxidants that affects signaling. For many enzymes, the cysteine is essential to activity, and oxidation to a sulfone or sulfinic acid causes inactivation. In general, cysteine residues are unreactive with superoxide or hydrogen peroxide at physiological pH. For cysteine to react with H_2O_2 , it must be either in a basic environment, where it becomes a thiyl anion, or in close association with a transition metal. Cysteine in the active site of some enzymes, such as protein tyrosine phosphatases, can be in the anionic state due to the surrounding microenvironment. This allows the cysteine to be susceptible to oxidation even when the protein is in a medium at physiological pH. The metal-catalyzed oxidation of cysteine is similar to the Fenton reaction [reaction (4b)] in which the sulfhydryl reduces the metal. Iron-sulfur clusters in the mitochondrial electron transport chain and aconitase are particularly susceptible to such chemistry. Interestingly, the loss of the iron-sulfur cluster in aconitase converts it to the active form of the iron response protein that affects transcription and translation of enzymes involved in iron metabolism. Nevertheless, the oxidation of cysteines through metal catalysis is not the only process that could produce changes in signaling through cysteine modification. As described above, nitrosation of cysteines is another possible mechanism, although specific examples in signaling are unknown at present.

Better established examples of modification of cysteine residues include those where the cysteines in the signaling proteins are in close proximity (referred to as vicinal thiols). The protein kinase C (PKC) α and β isoforms have clusters of cysteine residues in both the catalytic and regulatory domains. In the regulatory domain, cysteine residues associate with zinc, a nontransition metal, which while not redox active causes the cysteines to be in the anionic state. Addition of physiologically relevant concentrations of H_2O_2 to cells results in the oxidation of the vicinal cysteines in the regulatory domain to form disulfides, while the active site cysteines remain in their reduced state. The formation of cystine(s) in the regulatory domain brings about a conformational change in PKC so that it is active in the absence of calcium and phospholipid, normally required for its activity. This conversion is reversed by reduction of the cystine residue. This reversible activation suggests that PKC may participate in oxidant-initiated signaling. At higher concentrations of H_2O_2 , the cysteine in the active site of PKC can be oxidized irreversibly, thereby the result of a damaging reaction.

A reversible oxidation of cysteine residues occurs in the physiological reduction of H_2O_2 by thioredoxin (TRx), both nonenzymatically and enzymatically catalyzed by TRx peroxidases and glutathione peroxidases:

where $\text{TRx}(\text{SH})_2$ is reduced thioredoxin, TRxS_2 is thioredoxin disulfide, GSH is reduced glutathione, and GSSG is glutathione disulfide. The active sites of these proteins are basic microenvironments in which one of the cysteines can be ionized and therefore becomes reactive with H_2O_2 . Reaction (10) is catalyzed by thioredoxin peroxidases, and reaction (11) is catalyzed by glutathione peroxidases. Another class of enzymes, the peroxiredoxins, can use thioredoxin, glutathione, or other thiols to reduce hydroperoxides. The active form of some of these enzymes are homodimers in which each monomer contributes a critical cysteine to form a single active site with a vicinal thiol pair. Finally, some isoforms of glutathione-S-transferase can catalyze reaction (11) as well. The disulfides forms of thioredoxin and glutathione can then react reversibly with protein sulfhydryls:

where P symbolizes a protein and PSSG is a mixed disulfide. Reaction (12) can be catalyzed by protein disulfide isomerase (PDI), whereas reaction (13) may be nonenzymatic or possibly catalyzed by PDI. PDI itself has a reaction center that is quite similar to thioredoxin. If the resulting protein disulfide or mixed disulfide has enhanced or depressed enzymatic activity, reactions (12) and (13) may be the chemical steps whereby hydroperoxides transmit their signals in a reversible manner. In plants, the participation of thioredoxin in signaling is established, but in other systems it remains an interesting but unproven hypothesis. The glutathione mixed disulfides have similarly been investigated as signaling intermediates with little more than correlation as supporting evidence. For example, ultraviolet radiation produces reactive oxygen species that cause clustering and thereby activation of receptors in the absence of their natural agonists. These receptors include those that bind tumor necrosis factor α (TNF- α), EGF, and interleukin-1 (IL-1). Could this clustering result from disulfide formation?

Aside from vicinal thiol oxidation, there are several other examples where H_2O_2 has been demonstrated to activate enzymes directly. Cyclooxygenases (also called COX1 and COX2) catalyze the first step in the conversion of arachidonic acid to prostaglandins and related compounds, such as thromboxane. Lipoxygenases are responsible for initiating the production of leukotrienes from arachidonic acid. When cells are stimulated for the production of these arachidonic acid metabolites, these enzymes show a lag in their activity, which can be eliminated by the exogenous addition of very low concentrations of their products, lipid hydroperoxides or hydrogen peroxide. Products of the cyclooxygenase and lipoxygenase pathways are important agonists of receptor-mediated signal transduction affecting many physiological processes. Thus, the H_2O_2 -induced activation of these pathways may be one of the key mechanisms in oxidative signal-

ing. Another example of a direct effect of H_2O_2 activation is its effect on guanylate cyclase. Concentrations of H_2O_2 about 10–100 times those found during steady-state metabolism can activate guanylate cyclase by interacting with the same heme site where nitric oxide binds to produce its activating effect on guanylate cyclase. The extent to which this H_2O_2 -induced activation participates in normal physiology is unclear.

Intracellular Sources of Oxidants

Superoxide (and hydrogen peroxide) is produced in large amount by phagocytes (i.e., neutrophils and macrophages), not as the result of leaks or metabolic side reactions but through the deliberate induction of an enzymatic process as a defense mechanism for the killing and destruction of invading pathogens. The NADPH oxidase catalyzes the univalent transfer of an electron to oxygen at the expense of NADPH, its preferred substrate [reaction (14)]:

The NADPH oxidase is a multicomponent enzyme, which is dormant in resting cells and becomes active on assembly of the cytosolic and membrane components, the “phox” (phagocyte oxidase) proteins (Fig. 3). In the membrane, an atypical cytochrome b_{558} , composed of two subunits, gp91^{phox} and p22^{phox}, is the binding site for NADPH and flavin adenine dinucleotide (FAD), and it represents the terminal oxidase that transfers the electron to oxygen after assembly and activation. In the cytosol, p47^{phox}, p67^{phox}, and p40^{phox} are organized in a complex formed by protein–protein interaction through their proline-rich regions and *src* homology domain SH3, whereas the small GTP-binding protein of the Rho family Rac2 (or Rac1) is in a complex with the inhibitor Rho-GDI. On binding of various agonists to their cognate receptors or through membrane perturbation, the cytosolic phox proteins move to the membrane and associate with the flavocytochrome to form the activate oxidase (see Fig. 3 for details). Absence of either of the phox proteins leads to a genetic disease, chronic granulomatous disease (CGD), that is characterized by the inability of the phagocytes to produce superoxide and results in a high propensity to bacterial and fungal infections. All of the known phox proteins are now cloned, and tools have been developed, including CGD knockout mice that lack gp91^{phox} or p47^{phox}.

When the concept emerged that reactive oxygen and nitrogen species could serve as signaling molecules in processes such as proliferation and apoptosis, the search began for conditions under which production of these agents occurs in cells other than the phagocytes. This has been hampered by difficulties in accurately measuring low-level production in living cells and in defining the nature of the species involved. Fluorescent dyes that are freely permeable across cell membranes and increase in fluorescence on oxidation, such as 2',7'-dichlorofluorescein diacetate (DCF), have been used to measure oxidant production. DCF is oxidized through a reaction involving hydrogen peroxide and a per-

Figure 3 NADPH oxidase. This figure represents the cytosolic ($p47^{phox}$, $p67^{phox}$, and $p40^{phox}$) and membrane components ($gp91^{phox}$ and $p22^{phox}$) of the phagocyte NADPH oxidase in resting cells and after activation. The cytosolic components are organized in a large complex through protein–protein interaction via SH3 domains and proline-rich regions. In the cytosol, the small GTPase Rac1/2, which is required for oxidase activity, is associated with the inhibitor Rho-GDI. On stimulation, Rho-GDI dissociates and Rac moves to the membrane to bind the flavocytochrome. Stimulation also induces the phosphorylation of $p47^{phox}$ and changes in conformation leading to rearrangement of the complex through new protein–protein interactions. The cytosolic complex then moves to the membrane to bind to the flavocytochrome and Rac. The membrane complex represents the activated NADPH oxidase that catalyzes the reduction of oxygen to superoxide. The organization of the phox proteins in resting or activated cells has been extensively studied using a cell-free system and neutrophils from patients with chronic granulomatous disease (CGD), a genetic disease. Specific mutations in either of the core phox proteins have been identified, and the ability of the other proteins to translocate to the membrane has been studied. Although not shown on the figure, other data indicate that $p67^{phox}$ and the flavocytochrome become phosphorylated during activation.

oxidase, but it is not oxidized by superoxide. Hydroxyl radicals produced via Fenton chemistry [reaction (4b)] and peroxynitrous acid can also oxidize DCF. Thus, DCF oxidation does not discriminate among the reactive species. Nevertheless, using this tool, production of reactive oxygen species was detected in various cell types after stimulation with PDGF or EGF. Furthermore, Rac1, a small GTPase of the Ras superfamily, has been implicated as a regulator of reactive oxygen species (ROS) generation in fibroblasts, using constitutively activated (V12Rac1) or dominant-negative (N17Rac1) forms of Rac1. Production of superoxide under these conditions was inhibited by antioxidants and diphenylene iodonium (DPI), an inhibitor of flavoproteins. Rac is ubiquitously expressed, and it is a required participant in the assembly of the phagocyte NADPH oxidase, prompting the hypothesis that a flavoprotein, similar to that present in phagocytes, may be responsible for the production in nonphagocytic cells. In fact, immunologically related cytosolic oxidase components are found in some types of fibroblasts, endothelial cells, and epithelial cells, among others, and these cells produce low levels of superoxide. The flavocytochrome is an inducible protein and γ -interferon is known to

induce its expression. Although not fully explored yet, it is possible that other cytokines may also be effective. Thus, although preliminary at this point, these findings raise interesting possibilities and open new questions. The idea of an NADPH oxidase similar to that of phagocytes is intriguing; however, one should remember that patients with CGD experience only problems in relation with infection. Even wound healing problems are more likely due to the inability to clear an infection than to a proliferative repair problem. If the phagocyte NADPH oxidase were involved in many systems, one would expect more extensive defects. Although only reported in one study, the superoxide production of fibroblasts from a patient with CGD was normal. The role for a flavoprotein in nonphagocytic cells has been inferred in part from inhibition by DPI, which is not specific for the NADPH oxidase; indeed, DPI inhibits all flavoproteins and also reduces mitochondrial production of superoxide. More studies and better tools will be required to determine whether a related but differentially regulated NADPH oxidase is present in nonphagocytic cells. The fact that such an entity exists in plants, and that a $gp91^{phox}$ -related protein is expressed in yeast, suggests that the phagocyte NADPH

oxidase may have arisen with evolution from a more ancient and less toxic oxidase, which is still present in nonphagocytic cells.

Oxidants and Signaling Pathways

Much of the rest of this chapter is devoted to examples of signaling pathways in which oxidants have been proposed as participants.

Calcium Signaling

The steady-state intracellular free calcium ion concentration ($[Ca^{2+}]_i$) is 70–100 nM, which is 10^4 times lower than that of the plasma and most extracellular fluids. This is maintained by ion pumps, exchange with sodium, and sequestration within organelles (Fig. 4). Membrane receptor-mediated signaling involving elevation of $[Ca^{2+}]_i$ is initiated by the activation of a heterotrimeric G protein coupled to the receptor and activation of phospholipase C (Fig. 2). $[Ca^{2+}]_i$ elevation during signal transduction occurs through both release from the endoplasmic reticulum and opening of channels in the plasma membrane. The latter is signaled through changes in membrane potential, through G proteins coupled to receptors that act directly on channels, and through a response to emptying of the endoplasmic reticulum Ca^{2+} pool, which is still poorly understood. During physiological signaling, opening of plasma membrane Ca^{2+} channels results in small transient changes in $[Ca^{2+}]_i$. An ATPase (a calcium pump) maintains the endoplasmic reticulum pool of calcium through active import of the cation. Release from the pool occurs by activation of an IP_3 -sensitive receptor channel. Even in unstimulated cells, calcium is constantly released and taken up by the endoplasmic reticu-

lum. This basal release of Ca^{2+} from the endoplasmic reticulum occurs due to a low steady-state production of IP_3 .

Hydroperoxides have profound effects on the cellular control of calcium homeostasis. Exposure to high concentrations of hydroperoxides results in calcium entry through the plasma membrane and substantial elevation of $[Ca^{2+}]_i$, which is usually associated with cell death. On the contrary, addition of relatively low concentrations of hydroperoxides causes transient changes in $[Ca^{2+}]_i$ that resemble the physiological changes occurring in receptor-mediated signaling. The endoplasmic reticulum may contribute to this increase in $[Ca^{2+}]_i$, as an increase in glutathione disulfide observed during oxidative stress correlates with a decrease in the dissociation constant of the IP_3 receptor (and presumably involves formation of a mixed disulfide). Nonetheless, the hydroperoxide-induced increase in $[Ca^{2+}]_i$ can come from sources other than the endoplasmic reticulum and extracellular environment. In the alveolar macrophage, dissociation of annexin VI, a plasma membrane-bound calcium-binding protein, is the apparent hydroperoxide-sensitive source. Mitochondria as a source of calcium has been debated for a long time, but it is now clear that mitochondria only transiently take up calcium released by the proximate endoplasmic reticulum on stimulation. The extent of the involvement of this exchange between the endoplasmic reticulum and mitochondria during oxidative signaling is unknown. Suggestions that nitric oxide can signal calcium release from mitochondria are currently under investigation in several laboratories.

Some of the signaling mechanisms sensitive to the action of oxidants, which regulate $[Ca^{2+}]_i$ or are regulated by changes in $[Ca^{2+}]_i$, include phospholipases, prostaglandins, the constitutive form of nitric oxide synthetase, ion channels, classic forms of protein kinase C (α , β , and γ PKC), and calmodulin-dependent kinases. Although direct effects of hydroperoxides on calmodulin, the calcium-binding pro-

tein that acts as a nearly ubiquitous mediator of calcium-dependent functions, have not been demonstrated, the sensitivity of calmodulin to changes in $[Ca^{2+}]_i$ makes calmodulin-dependent activities, such as calmodulin-dependent kinases and protein phosphatase 2b, potential indirect targets of hydroperoxides through modulation of $[Ca^{2+}]_i$ (Fig. 2). Phospholipase D activity also appears to be enhanced by an elevation in $[Ca^{2+}]_i$ caused by low concentrations of hydroperoxides.

The MAP Kinase Pathways

Numerous cellular processes, such as cell growth, differentiation, cytoskeletal rearrangement, gene transcription, and apoptosis, are regulated through activation of the mitogen-activated protein kinase (MAPK) pathways (Fig. 5). Various receptors, namely, tyrosine kinase receptors, G-protein linked receptors, and others, activate these pathways, which are well conserved with evolution. Environmental stresses such as oxidant stress, heat shock, osmotic shock, or ionizing radiation can also trigger the activation of one or more MAPK pathways. Each pathway represents separate phosphorylation cascades or modules, at the center of which are the MAPKs, a large family of kinases that require concomitant phosphorylation on Thr and Tyr (TXY) by dual-specificity MAPK kinases or MEKs [MAPK–extracellular signal-regulated kinase (ERK) kinase] or MKKs (MAPKK) for full activation. The MEKs–MKKs, which are themselves activated by Ser/Thr phosphorylation by MAPK kinase kinases [MAP(3)Ks or MEKK], phosphorylate only very specific MAPKs. The MAPKs are proline-directed Ser/Thr kinases, and their known substrates are localized both in the cytosol and in the nucleus, where they translocate on activation. Thus, kinases and transcription factors are phosphory-

lated by activated MAPKs, leading to alteration in cellular function and gene transcription (see Fig. 6).

The MAPKs are grouped into several subfamilies according to their TXY phosphorylation site. At this time, three such subfamilies defining three separate pathways have been characterized in some detail: ERK1 and ERK2 (TEY), previously known as the p44 and p42 MAPKs, respectively; the *c-jun* N-terminal kinases or JNKs, also known as the stress-activated protein kinases or SAPKs (TPY); and the RK/p38 MAP kinases (TGY) (Fig. 5). The ERKs are preferentially

Figure 6 Transcription factors and MAP kinases. The proteins c-Jun and c-Fos (or members of their family) interact to form the AP-1 transcription factor that binds to the TRE *cis*-acting element and increases transcription of AP-1 responsive mRNAs, such as that for c-Jun itself. The proteins Elk-1 and the serum response factor (SRF) bind together with the serum response *cis*-acting element (SRE) to activate transcription of *c-fos*. The signaling pathways are described in the text.

activated by growth factors and are associated with cell growth and differentiation, whereas the JNKs and p38MAPKs are activated by cytokines and environmental stress in a cell-type specific manner and are implicated in apoptosis. MEK1 and MEK2 activate the ERKs, and recent data show that they are in a complex with a scaffold protein, MP-1, that maintains the core enzymes in close proximity. MEK1 and MEK2 are themselves activated by isoforms of Raf-1 or by Mos, forming the ERK module that is downstream of the protooncogene p21 Ras, a small GTPase. The connection between the receptor, Ras, and the ERK module is provided by the adapter Grb2, which is constitutively bound to the GDP exchange factor Sos through its SH3 domain and binds to the phosphorylated receptor either directly or through SHC, another adapter protein, via its Src homology SH2 domain. These protein–protein interactions lead to the activation of Ras by bringing its exchange factor Sos close to the membrane (Fig. 6).

Three JNK isoforms are currently identified, which are activated at least by two MEKs, MKK4 and MKK7. A scaffold protein, JIP-1, which was initially identified as an inhibitor of JNK, associates with JNK, MKK7, MLK, and HPK (see later in this chapter). The p38 MAPK subfamily is also composed of several isoforms (α to δ) and two MEKs, MKK3 and MKK6, are described so far as their activators. Upstream of the MEKs, the JNK and p38 pathways are not as clearly defined as the ERK pathway, and a large amount of cross talk between the two pathways seems to exist, that is, the same MAP(3)K can activate both the JNK and p38 pathways.

The MAP(3)Ks are structurally divergent and include MEKK1,2,3,4, MAP(3)K5/ASK-1, TAK1, MLK2,3, MUK/DLK, and Tlp2/Cot. They activate the MEKs *in vitro* and *in vivo*, with little specificity for the JNK or p38 MAPK pathways, except possibly for MEKK1, MLK2, and MLK3, which demonstrate more specificity for the JNK pathway. Upstream of the MAP(3)Ks, Rac1 and Cdc42Hs, members of the Rho subgroup of the Ras superfamily of GTPases, activate the JNK and p38 pathways *in vivo*, and their direct effectors, a family of p21-activated (PAK) kinases that possess a Cdc42/rac interaction domain (CRIB), activate the JNK and p38 pathways. There is no evidence that the PAKs directly activate the MAP(3)Ks.

The germinal center kinases (GCK), a large family of kinases distantly related to the PAKs but which lack a CRIB domain and do not bind to the Rho GTPases, are also upstream activators of the MAP(3)Ks and include the group I GCK, GCKR, GLK, HPK1, NIK, and group II SOK1, Krs-1, MST1/Krs2, MST3, and LOK. The group I of GCKs manifest selectivity for the JNK pathway over the p38 or ERK pathway. Interestingly, GCK, NIK, and HPK1 can bind MEKK1, and GCK and HPK1 bind MLK3 *in vivo* and *in vitro*.

The link between the events at the cell surface and the upstream activators of the JNK and p38 pathways is not known. There are also a number of “orphan” kinases for which the upstream activators are unknown such as ERK3,

which has no known activator or substrate, and ERK5, also known as BMK-1 (Big-MAPK-1), which is activated by MEK5.

The role of oxidants in the activation of these pathways is under extensive scrutiny. SOK-1 (ste20-like oxidant stress response kinase 1), a homolog of the yeast Sterile 20 family of protein kinases, and BMK-1 are relatively specifically activated by oxidant stress. In particular, SOK-1 is not activated by growth factors, and its activation does not result in the activation of any of the known MAP kinase cascades, suggesting that this kinase is part of a novel stress response pathway, yet to be identified.

Whereas growth factors do not activate the stress-activated kinases JNKs and p38, there is a strong consensus that exogenous H_2O_2 activates the ERKs in various cell types such as endothelial cells, smooth muscle cells, PC12 cells, and others, with doses as low as 25 μM in some cells. Although the ERK pathway participates in the induction of iNOS and production of NO, so far the data are scarce for the effects of NO on the ERK pathway; however, the JNKs appear to be more sensitive to activation by NO and other related species. Both JNKs and p38 are also activated by H_2O_2 , although the extent of activation of each pathway varies with the cell type. The lipid peroxidation product 4-hydroxynonenal (4HNE) strongly activates JNKs and p38 through increased production of H_2O_2 . The mechanisms by which the MAPKs are activated are still unclear. Current data show that they are not direct targets for oxidants and that upstream activators such as MEK1, MEK2, Raf, and MKK6 are similarly activated by H_2O_2 . An exception might be the recently described direct interaction of JNK1 with the lipid peroxidation product 4 HNE, which was shown to activate JNK without affecting its phosphorylation.

Several candidate molecules are currently under study as the potential upstream mediators of the effects of oxidants on these pathways. Tyrosine kinase inhibitors often inhibit the activation of the MAPKs by oxidants, suggesting activation of tyrosine kinase pathways. Membrane tyrosine kinase receptors for EGF or PDGF are activated by H_2O_2 in the absence of the ligand; however, at least for the EGF receptor, activation by H_2O_2 does not result in ERK activation. The tyrosine kinase *c-src* is implicated in the activation of ERK2 and BMK-1 by H_2O_2 . PKC, whose activity is altered by oxidants, phosphorylates and activates Raf-1 and ERKs. Dominant–negative mutants of Ras prevent the activation of the ERK pathway by oxidants. Thus, Ras was proposed as an oxidant sensor, in part because of a critical cysteine residue at position 118 that is regulated in a redox-dependent fashion and affects nucleotide exchange.

Overexpression of the GCK or other kinases upstream of the JNK/p38 pathways result in constitutively active kinases, which indicates either that they are bound to an inhibitor or that they are able to oligomerize. These mechanisms of activation may be at work on treatment with oxidants. In fact, both mechanisms have been demonstrated for the MAP(3)K ASK-1, which activates the MKK4/MKK7-JNK and MKK3/MKK6-p38 signaling cascades. ASK-1 has a cysteine-

rich domain in its N terminus, which is the binding site for TRx under reducing conditions. TRx is highly sensitive to oxidation by ROS, and its oxidation by H_2O_2 would result in its dissociation from ASK-1 and activation of the MKKs, making TRx a physiological inhibitor of ASK-1. The activation of ASK-1 would occur via dimerization of ASK-1, as observed in cells overexpressing ASK-1 and treated either with H_2O_2 or TNF- α . Another mode of upstream activation can be through generation of metabolites that affect the pathways. Arachidonic acid, a product of phospholipase A_2 , which is activated by H_2O_2 and other oxidants, activates the ERKs and the ERK module in various cell types. Ceramide is produced on treatment with H_2O_2 via an increase in sphingomyelin hydrolysis by the neutral sphingomyelinase, and ceramide activates the JNKs through activation of the MAP(3)K TAK1, leading to apoptosis.

Finally, another mode of regulation of the MAPKs by oxidants may involve the induction of dual-specificity phosphatases. This large family of phosphatases removes phosphate from both Thr and Tyr residues, and most of the family members are inducible proteins, initially identified as a gene induced by oxidant stress. The mitogen-activated protein kinase phosphatases (MKP) have different specificities for the various MAPKs and different subcellular localization. H_2O_2 and arachidonic acid induce the expression of MKP-1, and agents that increase the release of arachidonic acid stimulate MKP-1 induction and activation of the MAPKs. Thus, redox-sensitive molecules and lipid mediators may play a significant role in the mechanisms of activation by oxidants of the MAPKs.

Tyrosine Phosphorylation Pathways

Tyrosine phosphorylation has emerged as an important means by which cell function is regulated, and many of the effects exerted by oxidants appear to be mediated through deregulation of the balance between protein tyrosine kinases (PTKs) and protein tyrosine phosphatases (PTPs). Treatment of various cell types with exogenous oxidants results in an increase in the tyrosine phosphorylation of many proteins, implying that tyrosine kinases and tyrosine phosphatases are targets for the oxidants. This is supported by the fact that these effects are increased by sodium vanadate, which forms peroxyvanadate in the presence of H_2O_2 and is a very potent inhibitor of tyrosine phosphatases. The effect of oxidants is quite cell type specific, depending on the antioxidant capability of the cells and on the basal activity of the kinases and phosphatases. As an example, treatment of neutrophils with H_2O_2 will not result in the accumulation of tyrosine phosphorylated proteins, unless catalase is inhibited or sodium vanadate is present, indicating the powerful antioxidant and tyrosine phosphatase activities in these cells. The doses of exogenous oxidants required to observe any net effect on tyrosine phosphorylation vary greatly from cell to cell, ranging from 1 nM to 10 mM, and the consequences of treatment with oxidants also vary from proliferation to growth inhibition and apoptosis.

Although numerous PTPs have been identified, there is as yet little understanding of their mechanisms of activation and inactivation. The active site of PTPs contains an essential cysteine, which is sensitive to vanadate and peroxides of vanadate. The PTP catalytic activity involves the formation of a transient phosphoenzyme where the phosphate group is transferred to the cysteine residue. At physiological pH, the cysteine is a thiolate anion. *In vitro* incubation with H_2O_2 inhibits several PTPs, whereas large alkyl hydroperoxides do not, and serine/threonine phosphatases are not affected. Concentrations as low as 45 μM are able to rapidly and completely inactivate the PTP activity *in vitro*. The inhibition of PTPs is reversed by treatment with thiols, indicating that reversible oxidation and reduction of a single catalytic residue regulate the activity of PTPs. The thiolate anion is the target of H_2O_2 , which converts it to sulfenic acid (Cys-SOH), preventing the transfer of the phosphate group. Thus, oxidants can modulate the activity of PTPs through a direct and reversible mechanism and the overall redox state of the cells dictates the steady-state levels of active enzymes. Glutathione is the most likely intracellular reduced thiol that could reverse the inactivation of PTPs *in vivo* [reaction (15)]:

where P-SOH is a protein with a sulfenic acid residue and PSH is the cysteine containing form of the protein.

The activity of tyrosine kinases is also affected by reactive oxygen and nitrogen species. PTKs are grouped by the transmembrane receptor type, such as the receptors for growth factors (EGF, PDGF, NGF) and the nonreceptor PTKs, that is, the Src, Syk, or JAK families. Activation of the receptor PTKs on ligand binding involves dimerization of the receptors and activation of the tyrosine kinase activity, leading to transphosphorylation. The nonreceptor PTKs are involved in the signaling pathways triggered by receptors lacking intrinsic tyrosine kinase activity, such as G protein coupled receptors and cytokine receptors. Oxidants play a role in signaling by the EGF receptor. Stimulation of A431 cells with EGF induces a transient increase in the production of H_2O_2 , as measured by fluorescence with DCF. Addition of catalase inhibits the EGF-induced tyrosine phosphorylation of the EGF receptor and of phospholipase C- γ (PLC- γ), and these effects are dependent on the tyrosine kinase activity of the receptor. Exogenous H_2O_2 also induces the tyrosine phosphorylation and activation of the EGF receptor in A549 cells and other cells, resulting in the activation of PLC- γ but not that of other downstream signaling pathways. EGF stimulation of these cells results in growth inhibition, and a comparable inhibition is observed when cells are treated with H_2O_2 . This indicates that, in the absence of the ligand, oxidants can modulate cell growth. It is possible that oxidative modification of a reduced cysteine in the EGF receptor may reversibly affect its activation. Of interest, donors of nitric oxide inhibit the transphosphorylation of the EGF receptor in intact cells, and this effect is partially reversed by incubation with dithiothreitol (DTT), indicating the involvement of thiol groups and S-nitrosylation of the receptor.

Ligand binding of the T-cell and B-cell receptors induces an increase in tyrosine phosphorylation that involves the coordinated participation of several nonreceptor tyrosine kinases of the Src and Syk families and of the transmembrane tyrosine phosphatase CD45. Treatment of lymphocytes with H_2O_2 induces the activation of the PTK Syk family (i.e., Syk and ZAP-70) and the downstream signaling pathways, although 5–10 mM H_2O_2 is required. *In vitro* treatment with H_2O_2 of the immunoprecipitated Syk or ZAP-70 does not result in their activation; thus, H_2O_2 is likely to act indirectly through modulation of upstream activators. Inhibition of CD45 by oxidants may result in activation of the Syk family of PTKs, as they are activated by tyrosine phosphorylation. On the contrary, proper function of CD45 is required for the positive regulation of the Src kinases. CD45 is implicated in the dephosphorylation of a tyrosine residue that maintains the Src kinases in an inactivate state through intramolecular binding between the SH3 domain and the SH2-kinase linker. Release of this inhibitory conformation leads to partial activation of the Src kinases.

It was first reported that the activity of the Src kinases *lck* and *fyn*, and *Iyn* and *yes* is affected by H_2O_2 only in the presence of vanadate. However, others reported that *lck* is actually strongly activated by diamide and H_2O_2 alone. This activation does not require the dephosphorylation of the inhibitory tyrosine residue at the C terminus and may be the result of phosphorylation by another tyrosine kinase. Activation of the nonreceptor PTKs has been observed in cells other than lymphocytes, including in neutrophils. Exogenous addition of GTP γ S to electroporabilized neutrophils induces the production of reactive oxygen species via activation of the NADPH oxidase and increases protein tyrosine phosphorylation. Under these conditions, the tyrosine kinases *hck*, *syk*, and *blk* are activated, whereas *lyn* and *fgr* are inhibited. As in lymphocytes, the effects of the reactive oxygen species are indirect, as they do not activate these kinases *in vitro*. In addition, CD45 is also inhibited under the same conditions. Stimulation of intact neutrophils with phorbol esters, which also activates the NADPH oxidase, had a similar inhibitory effect on CD45 activity, although CD45 is also inhibited in CGD neutrophils, albeit to a lesser extent and with different kinetics than in normal neutrophils. This indicates that, although oxidants produced by the NADPH oxidase contribute to the regulation of CD45 activity, additional pathways are at play.

Tyrosine phosphorylation seems to be involved in the activation of phospholipase D (PLD) by oxidants. PLD catalyzes the formation of phosphatidic acid (PA) and choline from phosphatidylcholine. Phosphatidic acid may play a direct role in intracellular signaling and generates second messengers by conversion to 1,2-diacylglycerol by a PA-phosphatase or to lysophosphatidic acid by phospholipase A2. Two separate mammalian genes have been cloned, PLD1 and PLD2, and four regions highly conserved among isoforms were identified, including a weak pleckstrin (PH) homology domain, which may serve as the binding site for phosphatidylinositol 4,5-bisphosphate (PtdIns 4,5P₂), an ac-

tivator of all PLD isoforms. The regulation of agonist-induced PLD activation involves several PKC isoforms, the small GTP-binding proteins of the Rho and ARF (ADP-ribosylation factors) subfamilies, calcium, and tyrosine kinases and phosphatases. PKC is the major activator of PLD, and only the conventional Ca²⁺-dependent α and β isoforms are effective. PMA activates PLD, and PKC inhibitors inhibit *in vivo* activation; however, activation of PLD by PKC *in vitro* does not require phosphorylation. Thus, the mechanisms of regulation of PLD activity by PKC are still unclear. The involvement of RhoA and ARF was demonstrated, in part, by the use of C3 exoenzyme of *Clostridium botulinum*, which ADP-ribosylates and inhibits the Rho proteins, and brefeldin A, which inhibits ARF activation. Whereas agonist-stimulated activation of PLD by RhoA has been demonstrated, the evidence for that by ARF is limited.

Many growth factors that induce tyrosine phosphorylation also induce PLD activity. Treatment of various cell types with H_2O_2 or other oxidants results in activation of PLD that was sensitive to both tyrosine kinase and tyrosine phosphatase inhibitors but not to PKC inhibitors, indicating a predominant role for tyrosine phosphorylation in PLD activation by oxidants. In these studies, the PLD entity was not characterized other than as an enzymatic activity present in intact cells. It is now known that several PLD isoforms with different localization, substrate specificities, and mode of regulation exist in the same cell. The effects of H_2O_2 treatment on the activation of a rat brain PLD isoform, homologous to human PLD1, have been studied in fibroblasts, using immunoprecipitation with a specific antibody. These data showed that H_2O_2 activates PLD only in the presence of vanadate, resulting in the tyrosine phosphorylation of PLD1 and other associated proteins in the PLD1 immune complexes. The activation of PLD1 was partially inhibited by either PTK or PKC inhibitors, but it was 90% inhibited by combining both inhibitors, contrary to previous reports in other cell types. Thus, further studies aimed at identifying the PLD isoforms affected by H_2O_2 are probably forthcoming.

Thus, there are discrepancies among cell types about the mechanisms by which oxidants exert their effects and whether H_2O_2 can act alone or in concert with vanadate. However, there is mounting evidence that tyrosine phosphorylation is modulated by oxidants through activation of tyrosine kinases and inhibition of tyrosine phosphatases, which involves both direct effects on critical thiols in these enzymes and/or indirect effects by modulation of the upstream activators.

Activation of Transcription Factors

Oxidants activate several transcription factors in eukaryotic and bacterial systems. In eukaryotes, the transcription factors, nuclear factor- κ B (NF- κ B), activator protein 1 (AP-1), and the antioxidant response element binding protein (ARE) have been investigated (Fig. 7). Others have been described to a lesser extent.

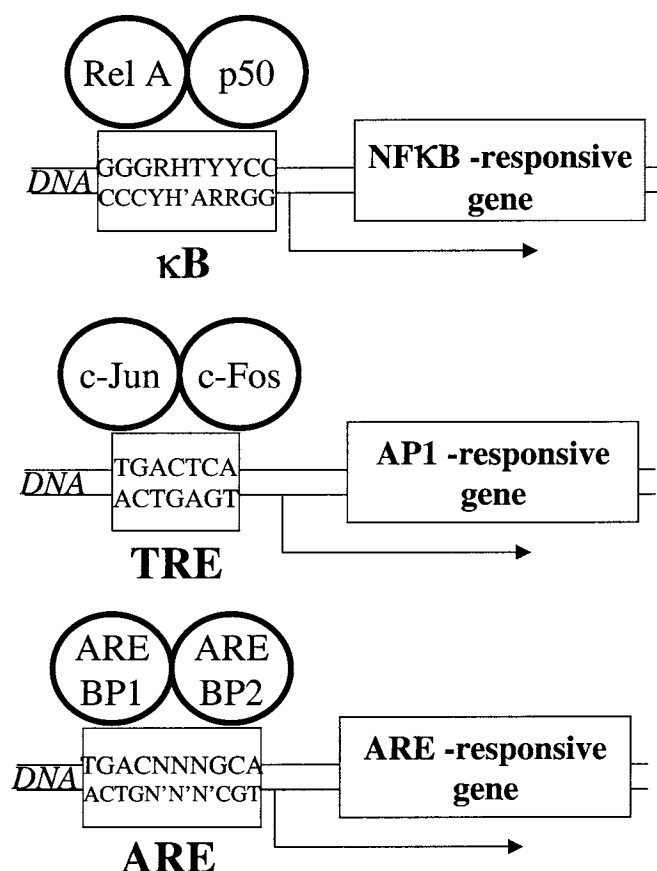

Figure 7 Oxidant-responsive *cis*-acting elements. See text for description of the transcription factors. The consensus sequences are shown.

NF-κB regulates transcription of several genes involved in inflammation, including TNF-α. Ultraviolet radiation, viruses, cytokines (such as TNF-α), phorbol esters, okadaic acid, and hydrogen peroxide can activate NF-κB. Interestingly, most of these stimuli appear to cause cells to produce reactive oxygen species. Nevertheless, separate hydrogen peroxide-dependent and -independent pathways for NF-κB activation can clearly exist within the same cell, and exogenous hydrogen peroxide does not stimulate NF-κB in all cell lines. NF-κB is found predominantly in the cytoplasm as a heterodimer of p65 (Rel A) and p50, complexed to the inhibitory subunit I-κB. On stimulation, I-κB dissociates, allowing NF-κB to migrate to the nucleus where it binds to DNA. In general, I-κB dissociation involves its phosphorylation on two serines, which marks it for ubiquitination and degradation, although tyrosine phosphorylation of I-κB may also permit its dissociation from NF-κB without subsequent degradation. NF-κB activation by reactive oxygen species is inferred from inhibition by antioxidants, including overexpression of catalase but not superoxide dismutase. The apparent mediator of oxidant-induced activation of NF-κB is hydrogen peroxide, but its primary site of action remains unclear.

The AP-1 transcription factor is often composed of the two well-known protooncogene products c-Fos and c-Jun.

These proteins are part of families that include Jun homologs and Fos-related activators (Fra), which form a variety of homo- and heterodimers that bind to DNA. There are two mechanisms whereby AP-1 becomes activated by oxidative stress. The first involves phosphorylation of the Jun proteins and their increased binding to DNA. The second involves the increased synthesis of Fos and Jun, so-called early response gene products. The binding of various combinations of the Fos/Jun family to AP-1 sites can either activate or inhibit transcription. Activation of AP-1 can be achieved through activation of the JNKs. Intriguingly, it appears that 4HNE, a product of lipid peroxidation, can directly activate JNK and increase transcription of 4HNE-responsive genes through Jun dimers, independently of JNK phosphorylation. The Ras–Raf–Erk pathway, which is activated by physiologically relevant generation of reactive oxygen species, results in phosphorylation of Elk-1, a transcription factor, which enhances production of Fos (Fig. 6). In addition, oxidants affect AP-1 mediated transcription by inhibiting the binding of AP-1 to DNA. This is a process that is regulated by the protein Ref-1, which catalyzes the reduction of a critical sulfhydryl involved in DNA binding.

Antioxidant responsive elements were first described in the promoter/enhancer regions of rat GSH-S-transferase Ya subunit and NAD(P)H:quinone reductase genes. Although ARE appears to have the ability to regulate transcription in response to oxidative stress, the details are still largely unresolved. Depending on the species and gene, ARE contains imperfect or perfect AP-1 binding consensus sequences. The transcription factor that specifically binds to the ARE has not been conclusively identified. Although c-Fos/c-Jun heterodimers have been ruled out as the activators of transcription by ARE, the interaction of Jun family proteins with members of the Nrf family of transcription factors seems likely.

Conclusions

Oxidants clearly participate in signaling a multitude of cell functions. In terms of their production, metabolic fate, and chemistry, superoxide, hydrogen peroxide, and peroxynitrite have most, if not all, of the essential characteristics of second messengers. The effectors of oxidant signaling include calcium-dependent enzymes, phospholipases, members of the MAP kinase family, protein tyrosine phosphatases, and several transcription factors. At present, we are beginning to determine the sites at which the oxidants act. Thus far, many involve the reversible oxidation of critical protein cysteine residues in the active sites of signaling enzymes. Nonetheless, we have only begun the journey down this stimulating pathway of biological discovery.

Mechanisms of Antioxidant Defense against Nitric Oxide/Peroxynitrite

Gavin E. Arteel, Karlis Briviba, and Helmut Sies

*Institut für Physiologische Chemie I
Heinrich-Heine-Universität Düsseldorf
Düsseldorf, Germany*

NITRIC OXIDE/PEROXYNITRITE CAN MEDIATE OXIDATION, NITRATION, OR NITROSATION REACTIONS, LEADING TO IMPAIRED FUNCTION, TOXICITY, AND ALTERATIONS IN SIGNALING PATHWAYS. DEFENSE AGAINST SUCH REACTIONS IS IMPORTANT FOR PROTECTION OF NORMAL TISSUE, ESPECIALLY DURING INFLAMMATION. ANTIOXIDANT DEFENSE IS ALSO EXPLOITED BY MICROORGANISMS TO PROTECT THEMSELVES AGAINST OXIDATIVE CHALLENGES FROM THEIR HOST OR THE ENVIRONMENT. BIOLOGICAL ANTIOXIDANT DEFENSE IS ORGANIZED INTO THREE CATEGORIES: PREVENTION, INTERCEPTION, AND REPAIR. PREVENTION IS THE CONTROL OF THE FORMATION OF NITRIC OXIDE AND/OR SUPEROXIDE AND THUS OF PEROXYNITRITE. INTERCEPTION IS BY DIRECT REACTION WITH NITRIC OXIDE, SUPEROXIDE, AND PEROXYNITRITE, LEADING TO NONTOXIC PRODUCTS. REPAIR PROCESSES REMOVE DAMAGE PRODUCTS AND RESTITUTE INTACT BIOMOLECULES. THIS CHAPTER SUMMARIZES THESE GENERAL STRATEGIES AND PRESENTS SOME SPECIFIC EXAMPLES RELATED TO NITRIC OXIDE AND RELATED SPECIES.

Nitric Oxide, Peroxynitrite, and Oxidative Stress

Nitric oxide¹ is a free radical containing an unpaired electron in the highest occupied molecular orbital. Nitric oxide is not a potent prooxidant in its own right; prooxidant effects are mediated predominantly by reaction products of nitric oxide with other molecules. Peroxynitrite is produced by the diffusion-limited reaction of nitric oxide and superoxide anion. Peroxynitrite is stable, but on protonation to peroxynitrous acid (pK_a6.8) it decays to nitrate, with a rate constant of 1.3 s⁻¹ at 25°C. Peroxynitrous acid is highly reactive, yielding oxidizing and nitrating species (see Beckman *et al.*, 1990; Koppenol *et al.*, 1992; Beckman, 1996; Koppenol, 1998; Murphy *et al.*, 1998). The combined effects of nitric oxide and peroxynitrite can be oxidation, nitration, as well as nitrosation reactions. Figure 1 shows some products of the reaction of peroxynitrite with biological molecules.

The balance between prooxidants and antioxidants is critical for survival and functioning of aerobic organisms. An imbalance favoring prooxidants and/or disfavoring antioxidants, potentially leading to damage, has been called oxidative stress (Sies, 1985, 1986, 2000). Nitric oxide serves as a useful illustration of this point. At the level of the whole organism, the reactive chemistry of nitric oxide/peroxynitrite can be considered beneficial. In addition to nitric oxide maintaining vascular tone, nitric oxide and derived species

¹ The systematic names of nitric oxide (NO•) and nitrosoperoxy carbonate (ONO₂CO₂⁻) are nitrogen monoxide and 1-carboxylato-2-nitrosodioxidane, respectively. The term peroxynitrite is sometimes used to refer to both the peroxynitrite anion proper (ONOO⁻) and peroxynitrous acid (ONOOH); the IUPAC names are oxoperoxonitrate(1-) and hydrogen oxoperoxonitrate, respectively.

Figure 1 Examples of products formed by nitrating/nitrosating reactions of nitric oxide/peroxynitrite.

(e.g., peroxynitrite) are cytotoxic to bacteria (Zhu *et al.*, 1992) or other invading organisms. Inflammatory cells, such as macrophages and neutrophils, produce large amounts of both nitric oxide and superoxide which, in turn, rapidly form peroxynitrite (Ischiropoulos *et al.*, 1992; Huie and Padmaja, 1993; Kissner *et al.*, 1997). However, excessive production can damage normal tissue. Indeed, the formation of protein 3-nitrotyrosine (Fig. 1), an index of reactive nitrogen species (Ohshima *et al.*, 1990), has been shown in a number of inflammatory conditions, a situation in which nitric oxide/peroxynitrite production is often increased (Ischiropoulos, 1998). Although the reactions mediated by nitric oxide/peroxynitrite include both reactive nitrogen and oxygen species, for simplicity, an imbalance favoring the production of any of these species will be referred to here as oxidative stress.

The physiological and pharmacological strategies for antioxidant defense are organized in three categories: prevention, interception, and repair (see Sies, 1993). This chapter will summarize these general strategies and present specific examples for nitric oxide and related species (Table I; see also Arteel *et al.*, 1999a). Microorganisms have also developed strategies to protect against killing by phagocytes and other cell types; this field of research is expanding rapidly (see Haas and Goebel, 1992; Nunoshiba *et al.*, 1993; De Groote *et al.*, 1997; Farrant *et al.*, 1997; Liochev *et al.*, 1999).

Mechanisms of Defense against Nitric Oxide/Peroxynitrite

Prevention

The first line of defense against reactive species is prevention against their formation by physical or biochemical means. An example of a physical defense can be avoidance, such as plankton submerging from the surface of seawater to lower levels of solar irradiation. Further, organisms design barriers to protect sensitive areas from reactive species. Barriers can be molecules (e.g., melanin in the skin), cells (e.g., intestinal mucosal cells with high turnover rates), or even organs (e.g., the “first pass effect” of liver removing ingested toxins from the portal blood).

Biochemical prevention refers to the control of the level of prooxidant or antioxidant proteins as well as small molecules maintained by an organism. For example, the concentration of free metal ions in the mammalian body is kept in check by metal-binding proteins, such as ferritin, transferrin, and metallothionein. As described for nitric oxide and superoxide synthesis (see later in this chapter), enzymes that produce potential prooxidants are generally under tight control, often with redundant mechanisms.

PREVENTION OF NITRIC OXIDE FORMATION

Obviously, prevention of the formation of nitric oxide will lead to a decrease in nitric oxide-derived reactive species. During inflammation, the expression of inducible nitric oxide synthase (NOS II) is often upregulated, concomitant with an increase in NOS activity. Further, the expression of “constitutive” nitric oxide synthases (NOS I and III) can also be upregulated by inflammatory cytokines (Förstermann *et al.*, 1998). In this context, suppressing the immune response may decrease nitric oxide formation and have a protective effect. Prevention at this level can include decreasing the immune stimulus (e.g., infection), preventing inflammatory cell recruitment, and/or suppressing activation of inflammatory cells. For example, the anti-inflammatory steroid budesonide has been shown to be protective against nitric oxide/peroxynitrite-mediated reactions and to decrease protein nitrotyrosine formation in human asthmatic patients (Saleh *et al.*, 1998). Even in the presence of a stimulated immune response, nitric oxide synthase inhibitors (e.g., N^G -monomethyl-L-arginine; L-NAME) can block the generation of nitric oxide and are protective in models of tissue damage (Matheis *et al.*, 1992; Cuzzocrea *et al.*, 1998).

PREVENTION OF SUPEROXIDE FORMATION

Because superoxide reacts with nitric oxide to form peroxynitrite, decreasing the formation of superoxide can also be a protective measure against nitric oxide/peroxynitrite-induced oxidative stress. Inhibition of enzymes that generate superoxide, for example, xanthine oxidase or NADPH oxidase, can be protective by preventing peroxynitrite formation (White *et al.*, 1996). Further, impairment of the immune response may also have a beneficial effect in

Table I Defense against Oxidant Effects of Nitric Oxide, Superoxide, and Peroxynitrite

^a Prevention suppresses the formation of nitric oxide and/or superoxide, and thereby peroxynitrite (see text).

^b Interception refers to small molecules and proteins that react directly with nitric oxide, superoxide, and/or peroxynitrite (direct), or prooxidants derived from these species (indirect) (see text).

^c Compounds involved in support and repair play a role in maintaining the antioxidative status of the cell and in repair of proteins and small molecules, once damaged by oxidative stress (see text).

decreasing superoxide production. It has been established that superoxide, directly or indirectly, can cause induction of the defensive SoxRS regulon in *Escherichia coli* (Liochev *et al.*, 1999).

PREVENTION OF PEROXYNITRITE FORMATION

Unlike the formation of nitric oxide and superoxide, peroxynitrite formation is an enzyme-independent process. Prevention of peroxynitrite formation thus focuses on pre-

venting the production of nitric oxide and/or superoxide, as described above, or on intercepting nitric oxide and superoxide (see later in this chapter).

Interception

The main point of this level of defense is to intercept a damaging species, once formed, so as to exclude it from further activity. Further, interception often leads to transfer

of the prooxidant away from more sensitive compartments of the cell. For determining the detoxifying capacity of a direct reaction of a given compound with a prooxidant, it is useful to consider the rate constant of this reaction and the achievable concentrations (see Table II). For homogeneous systems, multiplication of the concentration of a given compound with the corresponding second-order rate constant for the reaction with the prooxidant yields the rate of its disappearance. This first-approximation approach was previously used for considering the reaction of peroxynitrite with CO₂, hemoglobin, and peroxidases (Lyman and Hurst, 1996; Squadrito and Pryor, 1998; Arteel *et al.*, 1999a).

In addition to the rate with which a putative antioxidant interception reaction occurs, it is also useful to consider whether this reaction can be catalytically maintained. For example, melatonin has been shown to react with peroxynitrite (Gilad *et al.*, 1997); however, this reaction leads to a loss of the parent molecule via oxidation reactions (Zhang *et al.*, 1998), requiring *de novo* synthesis of more melatonin by the organism. Further, given the low concentrations in the body (with the exception of the pineal gland), it is unlikely that the reaction of melatonin with peroxynitrite is a predominant reaction pathway. It is likely that the protective effect of melatonin observed in *in vivo* models of inflammation

(Cuzzocrea *et al.*, 1997) is related to its indirect antioxidant effects [e.g., stimulation of superoxide dismutase (SOD) production and inhibition of nitric oxide production; for review, see Reiter *et al.*, 1998] and not direct interception.

DIRECT REACTIONS: SMALL MOLECULES

Scavengers of Nitric Oxide Exogenous scavengers of nitric oxide (e.g., 2-phenyl-4,4,5,5-tetramethylimidazoline-1-oxyl-3-oxide; carboxy-PTIO) react with nitric oxide. This effect may prevent excessive concentrations of nitric oxide during inflammation and subsequent formation of more potent prooxidants such as peroxynitrite. Inactivators of nitric oxide have been shown to be protective in animal models of inflammation, decreasing nitrotyrosine formation and the severity of tissue damage (Hooper *et al.*, 1997).

Carbon Dioxide Considering the concentration of carbon dioxide *in vivo* (~1 mM) and the rate constant of its reaction with peroxynitrite (Table II; Lyman and Hurst, 1995; Denicola *et al.*, 1996), the formation of the adduct nitrosoperoxycarbonate (ONO₂CO₂⁻) is most likely a major route of peroxynitrite reactivity *in vivo*. However, whether the carbon dioxide/peroxynitrite reaction is a detoxication pathway *in vivo* is unclear (Lyman and Hurst, 1996). For example,

Table II Interception of Peroxynitrite by Small Molecules and Proteins

Addition	Rate constant ^a (M ⁻¹ s ⁻¹)	<i>In vivo</i> concentration (M)	Disappearance of peroxynitrite (s ⁻¹)
Spontaneous decay	—	—	0.4
Small molecules			
Carbon dioxide	3.0 × 10 ⁴ (Denicola <i>et al.</i> , 1996)	1 × 10 ⁻³	30
Glutathione	5.8 × 10 ³ (Lee <i>et al.</i> , 1997)	1 × 10 ^{-2b}	5.8
Ascorbate	5.0 × 10 ⁴ (Bartlett <i>et al.</i> , 1995)	1 × 10 ^{-2c}	0.5
Ebselen	2.0 × 10 ⁶ (Masumoto <i>et al.</i> , 1996)	—	—
Metalloporphyrins	2 × 10 ⁶ (Lee <i>et al.</i> , 1997, 1998a)	—	—
Proteins			
Myeloperoxidase	4.8 × 10 ⁶ (Floris <i>et al.</i> , 1993)	5 × 10 ^{-4d}	2400
Hemoglobin	2.5 × 10 ⁴ (Alayash <i>et al.</i> , 1998)	5 × 10 ^{-3e}	125
Glutathione peroxidase ^f	8.0 × 10 ⁶ (Briviba <i>et al.</i> , 1998a)	2 × 10 ^{-6g}	16
Albumin	5.6 × 10 ³ (Radi <i>et al.</i> , 1991a)	6 × 10 ^{-4h}	3.4

^a Second-order rate constants are for pH 7.4, 25°C, with the exception of myeloperoxidase, which was at 12°C, and hemoglobin and albumin, which were at 37°C.

^b Concentration in hepatocytes.

^c Concentration in neutrophils.

^d Concentration in neutrophils. The concentration is calculated from the amount of myeloperoxidase per neutrophil (~1.5 × 10⁻¹⁶ mol) and neutrophil volume (~300 fl).

^e Concentration in erythrocytes.

^f Rate constant for the reduced form of glutathione peroxidase. The rate constant for oxidized glutathione peroxidase is 7.4 × 10⁵ M⁻¹ s⁻¹ at pH 7.4, 25°C (Briviba *et al.*, 1998a).

^g Concentration in hepatocytes. The concentration is calculated from the amount of selenium in liver (~2.6 mg liter⁻¹) (Behne and Wolters, 1983), assuming 23% to be present as GPx (Burk and Gregory, 1982).

^h Concentration in serum.

carbon dioxide enhances protein tyrosine nitration by peroxynitrite (Gow *et al.*, 1996). Further, whereas carbon dioxide decreases two-electron oxidation of thiols by peroxynitrite (Denicola *et al.*, 1996), one-electron oxidation reactions are enhanced (Scorza and Minetti, 1998). The latter pathway would lead to thiyl radical formation and subsequent radical chain reactions. Thus, it may be appropriate to call carbon dioxide a modifier of peroxynitrite reactions rather than a detoxifier.

Thiols and Uric Acid The formation of nitrosothiols by nitric oxide may be an important way to extend the lifetime of nitric oxide *in vivo* (Ignarro *et al.*, 1981; Marshall and Kontos, 1990; Stamler *et al.*, 1992a,b). This reaction may be considered as an interception in the context that nitrosothiol formation may allow nitric oxide to diffuse away from the site of synthesis, often colocalized with superoxide formation (Ischiropoulos *et al.*, 1992). This could thereby prevent the formation of peroxynitrite. S-Nitrosylated thiols may also cause oxidative modifications of proteins independent of the release of nitric oxide (Ji *et al.*, 1999). The interaction of peroxynitrite with free thiols in proteins (see later in this chapter) or in glutathione is also rapid enough (Table II; Radi *et al.*, 1991a) in view of their *in vivo* concentrations (millimolar range) to make this reaction significant (Koppenol *et al.*, 1992). Although the bulk of the reaction is a two-electron oxidation by peroxynitrite, at least a portion reacts via a one-electron pathway, leading to a sulfur-centered radical (Quijano *et al.*, 1997). Uric acid also reacts with peroxynitrite to form a vasoactive nitrated/nitrosated product (Fig. 1) and could thereby be a detoxication pathway of peroxynitrite (Skinner *et al.*, 1998).

Organoselenium Compounds: Ebselen Selenium-containing amino acids and the organoselenium compound ebselen (Fig. 2) rapidly react with peroxynitrite (Briviba *et al.*, 1996; Masumoto and Sies, 1996; Sies and Masumoto, 1997). The rate constant of the reaction of ebselen with peroxynitrite is $2.0 \times 10^6 \text{ M}^{-1} \text{ s}^{-1}$ (25°C, pH 7.4; Masumoto *et al.*, 1996), and ebselen protects against DNA damage caused by peroxynitrite more effectively than their sulfur analogs (Roussyn *et al.*, 1996). The reaction scheme depicted in Fig. 3 applies generally to ebselen or to selenocysteine in free or protein-bound form, such as in glutathione peroxidase (see later in this chapter). Peroxynitrite is reduced to nitrite by these compounds; the resulting selenoxide is subsequently reduced by GSH, establishing a catalytic cycle so that the defense can be maintained in a peroxynitrite reductase reaction. Organotellurium compounds also protect against oxidation and nitration reactions caused by peroxynitrite (Briviba *et al.*, 1998b, 1999; Jacob *et al.*, 2000); bis(4-aminophenyl) telluride protects against peroxynitrite-mediated oxidation of dihydrorhodamine 123 more efficiently than its selenium analog or ebselen (Briviba *et al.*, 1998b).

Clinically, ebselen has been found to be protective in patients with delayed neurological deficits and aneurysmal subarachnoid hemorrhage (Saito *et al.*, 1998), in acute

Figure 2 Structures of some low-molecular-weight compounds with high second-order rate constants for the reaction with peroxynitrite, including organoselenium, organotellurium, and synthetic metal porphyrin compounds (see Table II).

Figure 3 Proposed catalytic mechanism of selenoperoxidases in the reduction of peroxynitrite to nitrite (or peroxynitrous acid to nitrous acid). The mechanism is based on that established for glutathione peroxidases and the mimic, ebselen, which use ROOH and ROH as substrate and product, respectively (see Masumoto and Sies, 1996; Sies *et al.*, 1997). Selenomethionine can also react with peroxynitrite, with the resultant methionine selenoxide being reduced by glutathione in a catalytic cycle (Assmann *et al.*, 1998).

ischemic stroke (Yamaguchi *et al.*, 1998), and in acute middle cerebral artery occlusion (Ogawa *et al.*, 1999). The clinical development of ebselen has been reviewed (Parnham and Sies, 2000). Because increased nitrotyrosine levels were found to be associated with such neurological disorders, these protective effects of ebselen could be due in part to peroxynitrite defense.

Metalloporphyrins Synthetic metalloporphyrins (Fig. 2) may defend against prooxidant effects of nitric oxide/peroxynitrite at several levels. First, they are superoxide dismutase mimics, and thereby may decrease the amount of peroxynitrite formed. They also react with peroxynitrite at second-order rate constants similar to that of ebselen (Table II; Stern *et al.*, 1996; Lee *et al.*, 1997). The metal in the porphyrin shown in Fig. 2 can be manganese(III) or iron(III). Both compounds catalyze the isomerization of peroxynitrite to nitrate. It is proposed that peroxynitrite attacks the metal, and the manganese(IV) can be reduced by thiols or ascorbate (Lee *et al.*, 1997, 1998a); on the other hand, the respective iron(IV) compound catalyzes its own reduction (Stern *et al.*, 1996; Lee *et al.*, 1998b). Synthetic porphyrins have been shown to be cytoprotective against peroxynitrite *in vitro* (Misko *et al.*, 1998) and to alleviate some of the toxic effects of endotoxic shock in rats (Zingarelli *et al.*, 1997). It should be mentioned that nitrogen dioxide can be released during the reaction process (Lee *et al.*, 1997, 1998b), and that these compounds may enhance nitration reactions of peroxynitrite (Ferrer-Sueta *et al.*, 1997), so that toxicity might become an issue.

DIRECT REACTIONS: PROTEINS

Heme Peroxidases The mammalian heme peroxidases (e.g., myeloperoxidase; Floris *et al.*, 1993) also react with peroxynitrite (Table II). Although the concentration of myeloperoxidase in blood is low relative to more abundant biomolecules that react with peroxynitrite (e.g., CO₂; Squadrito and Pryor, 1998), concentrations are much higher in inflammatory cells (e.g., neutrophils; Table II). Further, localized extracellular concentrations near inflammatory cells during the respiratory burst may be high enough to react with peroxynitrite. In plants, the reaction between horseradish peroxidase and peroxynitrite may also be significant; the rate constant is $3.2 \times 10^6 \text{ M}^{-1} \text{ s}^{-1}$ at pH 6.8, 25°C (Floris *et al.*, 1993). The reaction of horseradish peroxidase can be catalytically maintained using chlorogenic acid as a reductant (Grace *et al.*, 1998). However, both myeloperoxidase and horseradish peroxidase increase formation of nitrotyrosine by peroxynitrite (Sampson *et al.*, 1996).

Hemoglobin Oxyhemoglobin reacts with nitric oxide to methemoglobin and nitrate via a short-lived intermediate peroxynitrite complex (Herold, 1998), and it may play an important role in regulating concentrations of nitric oxide in blood. The biology and chemistry of the interaction of NO and hemoglobin are reviewed in more detail elsewhere (see

Stamler and McMahon, Chapter 15, this volume). Hemoglobin also reacts rapidly with peroxynitrite and is suitable for efficient protection of erythrocytes. However, hemoglobin is not able to fully protect the plasma membrane of erythrocytes; when peroxynitrite was generated outside the cells, hemolysis was found to occur (Kondo *et al.*, 1997).

Selenoproteins The selenocysteine-containing glutathione peroxidase (GPx) can act as a peroxynitrite reductase, preventing oxidation and nitration reactions caused by peroxynitrite (Sies *et al.*, 1997). Glutathione peroxidase reduces peroxynitrite to nitrite using GSH in a catalytic reaction at a stoichiometry of 1:2, the same as that of hydroperoxide reduction, that is, the classic GPx reaction (Fig. 3), and similar to that described above for ebselen, and also for selenomethionine. Increases in nitrite during exposure to peroxynitrite were observed with GPx (Sies *et al.*, 1997), indicating two-electron reduction of peroxynitrite; however, the nitrite yield was less than complete (~50%). The second-order rate constant for the reaction of glutathione peroxidase (tetrameric) with peroxynitrite is $8.0 \times 10^6 \text{ M}^{-1} \text{ s}^{-1}$ (Briviba *et al.*, 1998a). Although there is no net loss of GPx activity when GPx is maintained in the reduced state by supplying reductants (Sies *et al.*, 1997; Briviba *et al.*, 1998a), GPx is inactivated in the absence of GSH (Padmaja *et al.*, 1998) or on exposure to nitric oxide donors (Asahi *et al.*, 1997). These data suggest that inside the cell, GPx outcompetes thiols for the direct reaction with peroxynitrite (Table II). It was also shown that increasing the level of selenoproteins (e.g., GPx 14-fold) by selenium supplementation attenuated mitogen-activated protein kinase (p38, JNK1/2, and ERK1/2) activation by peroxynitrite in WB-F344 rat liver cells (Schieke *et al.*, 1999). Selenium supplementation also prevents decreases in gap junctional intracellular communication caused by peroxynitrite (Sharov *et al.*, 1999). Thus, the reaction of GPx with peroxynitrite is considered a biologically efficient detoxication pathway *in vivo*.

Selenoprotein P in human plasma also protects against peroxynitrite (Arteel *et al.*, 1998), suggesting that it may serve as a protectant against peroxynitrite in human blood. The heparin-binding domains of selenoprotein P enable surface coating of cellular membranes (e.g., endothelial cells; Wilson and Tappel, 1993; Burk *et al.*, 1997). This coating may serve as a protective barrier against peroxynitrite. Selenoprotein P was also shown to serve a function as an extracellular phospholipid hydroperoxide glutathione peroxidase using thiols as reductants (Saito *et al.*, 1999); this function may also make selenoprotein P important in removal of potential free radical products of nitric oxide/peroxynitrite (see later in this chapter).

The selenoprotein thioredoxin reductase can function in the reduction of peroxynitrite by selenocysteine or ebselen (Arteel *et al.*, 1999b). Although the thioredoxin system (NADPH, thioredoxin reductase, and thioredoxin) has been shown to directly reduce lipid hydroperoxides (Mitsui *et al.*, 1992; Björnstedt *et al.*, 1995), the reaction rate is relatively

slow. However, the ability of the thioredoxin system to reduce more potent antioxidants may be biologically significant. For example, ascorbate (Mendiratta *et al.*, 1998), glutathione peroxidases (Björnstedt *et al.*, 1994), and thioredoxin peroxidases (Cha and Kim, 1995) are reduced by the thioredoxin system. In this context, the thioredoxin system can contribute to antioxidant defense and play a specific role in peroxynitrite defense.

Selenomethionine (Fig. 2) is oxidized to the selenoxide by peroxynitrite with a second-order rate constant approximately 100-fold higher than that for the reaction of methionine with peroxynitrite (Padmaja *et al.*, 1996). Methionine selenoxide is effectively and rapidly reduced to selenomethionine by glutathione, permitting a catalytic reaction by selenomethionyl residues in proteins (Assmann *et al.*, 1998). In contrast, methionine sulfoxide is not reduced by glutathione; the enzyme methionine sulfoxide reductase is necessary for the reduction of methionine sulfoxide to methionine (Levine *et al.*, 1996). Because selenomethionine can occur in proteins such as hemoglobin (Beilstein and Whanger, 1986), these residues may play a defensive role against peroxynitrite. However, work by Hondal *et al.* (1999) failed to show protection against peroxynitrite by selenomethionine residues in albumin and IgG.

Albumin The reaction product of nitric oxide and the reactive cysteine in albumin is highly stable and may increase the diffusion distance of nitric oxide *in vivo* (see earlier in this chapter; Stamler *et al.*, 1992a,b). Further, the high concentration of albumin in blood (millimolar) makes its reaction with peroxynitrite significant (Table II; Radi *et al.*, 1991a). Whereas the reaction of peroxynitrite with albumin is largely due to the one free cysteine residue (Radi *et al.*, 1991a), human albumin also contains six tyrosine residues adjacent to glutamate residues, which are preferentially nitrated by peroxynitrite (Beckman, 1996). Indeed, oxidized (Scorza and Minetti, 1998) and nitrated (e.g., Arteel *et al.*, 1998) products of albumin are observable when peroxynitrite is added to plasma.

Superoxide Dismutase Superoxide dismutase decreases superoxide levels (McCord and Fridovich, 1969) and thereby can prevent peroxynitrite formation (White *et al.*, 1994). Expression of superoxide dismutase can be induced by proinflammatory cytokines (Wong and Goeddel, 1988), possibly conferring protection to normal tissue during inflammation. Furthermore, superoxide dismutase reacts with peroxynitrite, catalyzing the nitration of tyrosine residues (MacMillan-Crow *et al.*, 1996, 1998). However, this reaction inactivates Mn-SOD (MacMillan-Crow *et al.*, 1998) and has been linked to renal allograft failure in humans (MacMillan-Crow *et al.*, 1996); this reaction therefore may well not be a detoxification pathway.

In contrast to Mn-SOD, nitration of Cu,Zn-SOD by peroxynitrite does not inactivate the protein (Smith *et al.*, 1992). The glycosylated extracellular Cu,Zn-containing SOD

(ecSOD) binds glycosaminoglycans (Karlsson *et al.*, 1988) and coats endothelial cells (Karlsson and Marklund, 1989). This mechanism may also be a defensive barrier in endothelial cells, analogous to that discussed earlier for selenoprotein P. The expression of ecSOD is upregulated in atherosclerotic plaques, and it is colocalized with iNOS and modified lipids (Luoma *et al.*, 1998). Further, Cu,Zn-SOD has been shown to reversibly convert nitric oxide to nitroxyl anion (NO^-) (Murphy and Sies, 1991). Analogous to nitrosothiol formation (see earlier in this chapter), this reaction may allow nitric oxide to diffuse away from the site of synthesis, contributing to the prevention of peroxynitrite formation.

INDIRECT REACTIONS

In addition to direct interception of prooxidants, biological molecules can react with products of oxidative stress and thereby play a role in defense. Further, there are proteins and molecules that have supportive roles in maintaining the antioxidative status of the cell, forming a veritable antioxidant network.

Glutathione and Ascorbate In addition to reacting directly with nitric oxide and peroxynitrite, glutathione (see earlier in this chapter) is a potent intracellular reductant and helps to maintain catalytic antioxidant reactions (e.g., coupled with glutathione peroxidase as discussed above; see Fig. 3). For a general discussion on the role of glutathione in cellular functions, see Sies (1999). Ascorbate has a low second-order rate constant for the reaction with peroxynitrite (Table II; Bartlett *et al.*, 1995) and is relatively unreactive with nitric oxide (Jackson *et al.*, 1998). Even with millimolar concentrations in cells, it is therefore unlikely that ascorbate plays a significant role in direct reactions with peroxynitrite or nitric oxide. However, in reducing chain-breaking antioxidants, such as tocopherol (Leung *et al.*, 1981; Scarpa *et al.*, 1984; Niki, 1987; Wefers and Sies, 1988), oxidized metalloporphyrin compounds (Lee *et al.*, 1997, 1998a), or heme-containing proteins attacked by nitric oxide/peroxynitrite, ascorbate can play an important role in antioxidant defense against nitric oxide/peroxynitrite.

Flavonoids, Carotenoids, and Tocopherols Flavonoids are natural products found in plants, and these polyphenols are ingested with the diet. Flavonoids are general free radical scavengers, and they chelate transition metals (Morel *et al.*, 1993; Jovanovic *et al.*, 1994; De Groot and Rauen, 1998); both functions may indirectly assist in defense against oxidative stress caused by nitric oxide/peroxynitrite. Flavonoids also react with nitric oxide (van Acker *et al.*, 1995), superoxide (Robak and Gryglewski, 1988; Girard *et al.*, 1995), and protect against oxidation and nitration reactions caused by peroxynitrite (Haenen *et al.*, 1997; Pannala *et al.*, 1997; Arteel and Sies, 1999). It is likely that these compounds react with nitrating and oxidizing intermediate species formed during peroxynitrite decay, and not with peroxynitrite

proper, similar to simple phenolic compounds (Ramezani *et al.*, 1996). However, due to their protective effects, they can thereby play a role in nitric oxide/peroxynitrite protection.

Carotenoids (e.g., β -carotene) are also potent general antioxidants (Stahl and Sies, 1994), reacting with nitric oxide and superoxide (Zhao *et al.*, 1998), and they protect against reactions of peroxynitrite and nitrogen dioxide (Kikugawa *et al.*, 1997; Zhao *et al.*, 1998). In addition to their free radical chain-breaking abilities, tocopherols (e.g., γ -tocopherol) react with nitric oxide (De Groot and Sies, 1993) and protect against peroxynitrite and other reactive nitrogen species (Hogg *et al.*, 1993; Christen *et al.*, 1997; Fig. 1), and they may assist in protecting lipid membranes from attack by nitric oxide/peroxynitrite. As β -carotene and γ -tocopherol are chemically modified by the reaction with peroxynitrite (Kikugawa *et al.*, 1997; Christen *et al.*, 1997), the question arises whether there is a possibility for regeneration of these micronutrients, which occurs only at very low concentrations in cells and tissues.

General Free Radical Scavengers As mentioned previously, the reaction of peroxynitrite with biological molecules (e.g., thiols) can lead to the formation of free radicals and initiate radical chain reactions. Therefore, free radical scavengers not specific to nitric oxide, superoxide, or peroxynitrite (e.g., ubiquinol-10, and bilirubin; Table 1) may also play a role in defense against damage due to peroxynitrite. α -Tocopherol is an effective chain-breaking antioxidant and may help limit lipid peroxidation due to oxidative stress caused by nitric oxide/peroxynitrite. It is of interest that whereas products of nitric oxide may stimulate lipid peroxidation (Radi *et al.*, 1991b), nitric oxide itself can also serve as a radical chain-breaking antioxidant during lipid peroxidation (Rubbo *et al.*, 1994; Gutierrez *et al.*, 1996).

Proteins Proteins can also play a role in indirectly decreasing the prooxidant effects of nitric oxide/peroxynitrite. For example, hydroperoxides and lipid hydroperoxides are often products formed during oxidative stress, for example, during excessive nitric oxide/peroxynitrite production (Radi *et al.*, 1991b). In this context, peroxidases and catalase can play a major role in defense (Chance *et al.*, 1979). Given that heme peroxidases and selenoperoxidases react directly with peroxynitrite, these enzymes play a dual role in antioxidant defense.

Another important ancillary protein is GSSG reductase, which maintains the glutathione pool in the reduced state at the expense of NADPH. In addition to the reactions mentioned previously, the thioredoxin system also helps maintain cellular thiol pools in the reduced state at the expense of NADPH (Björnstedt *et al.*, 1997). By extension, proteins responsible for maintaining cellular energy status and NADPH supply are also important. An illustration of this latter point is the fact that cells depleted of their glycogen reserves are more prone to oxidant insults than glycogen-replete cells (Smith *et al.*, 1987). As mentioned previously,

proteins involved in chelating free metals constitute an indirect antioxidant defense, especially considering the fact that reactions of nitric oxide and peroxynitrite can be catalyzed by metals. Lastly, transport systems responsible for removing reactive compounds from the cells are also important, for example, the glutathione *S*-transferases and the transport systems for glutathione *S*-conjugates (Sies and Ketterer, 1988).

Repair

Protection from the effects of oxidative stress can be by repair of damage once it has occurred or by protection from further damage (e.g., 8-oxo-7,8-dihydroguanine). As prevention and interception processes are not completely effective, damage products could continuously form in low yields during excessive nitric oxide/peroxynitrite generation and may accumulate. Damaged biomolecules include the following: DNA, occurring as modified bases (Yermilov *et al.*, 1995; Douki and Cadet, 1996; Douki *et al.*, 1996; Spencer *et al.*, 1996; Fig. 1) or in the form of single- or double-strand breaks (Szabó and Ohshima, 1997) leading to increased mutagenicity (Juedes and Wogan, 1996), similar in pattern to that observed with singlet oxygen (Ribeiro *et al.*, 1992); membranes, occurring as phospholipid oxidation and nitration products (Fig. 1; O'Donnell *et al.*, 1999); and proteins, occurring as oxidized and nitrated amino acid side chains. Correspondingly, there are biological systems that are capable of providing the functions of restitution or replenishment. 3-Nitrotyrosine denitrase activity has been identified in rat tissues (Kamisaki *et al.*, 1998), enabling cells to remove this damage from proteins.

Biomolecules damaged by nitric oxide/peroxynitrite may not be easily repaired. Under these conditions, the degradation of damaged molecules may be enhanced. For example, modification of lipoproteins by nitric oxide/peroxynitrite leads to recognition and uptake by macrophages, increasing their turnover rate relative to unmodified lipoproteins (Graham *et al.*, 1993; da Silva and Abdalla, 1998). The degradation of proteins such as aconitase by proteasomes is enhanced on treatment with peroxynitrite (Grune *et al.*, 1998). The emerging and active field of research on repair of nitric oxide/peroxynitrite-induced damage is not reviewed in detail here.

Concluding Remarks

Antioxidant defense against nitric oxide/peroxynitrite occurs by multiple strategies and at various levels. Further, the compartmental nature of cell systems may make one type of defense more prevalent than others in different areas of the cell. Understanding of general principles of antioxidant defense, as well as mechanisms of defense specific against certain reactive species, can be used as a predictive tool for pharmacologic measures that may be useful in models of overproduction of nitric oxide/peroxynitrite.

University of Buenos Aires, Buenos Aires, Argentina*

A CLASSIC PHYSIOLOGICAL PARADIGM WAS THE STABILITY OF MOLECULAR OXYGEN (O_2) UPTAKE UP TO VERY LOW HYPOXIC O_2 TENSIONS. THE NOTION WAS SUPPORTED BY THE VERY LOW K_m FOR O_2 OF MITOCHONDRIAL CYTOCHROME OXIDASE. RECENTLY, NITRIC OXIDE WAS SHOWN TO REVERSIBLY INHIBIT CYTOCHROME OXIDASE AFTER BINDING TO THE ENZYME WITH EVEN GREATER AFFINITY THAN O_2 ; HENCE, O_2 UPTAKE BECAME DEPENDENT ON THE O_2 :NO RATIO. TO DEFINE A REGULATORY MECHANISM, IT WAS FURTHER REQUIRED THAT A FAST DISSOCIATION OF NO–CYTOCHROME COMPLEX FOLLOWING REMOTION OF NO COULD OCCUR. ACCORDINGLY, WE OBSERVED THAT NO ELICITS A STOICHIOMETRICAL PRODUCTION OF SUPEROXIDE ANION IN MITOCHONDRIA BY REACTING WITH MEMBRANE-BOUND UBIQUINOL; CONSEQUENTLY, NO LARGELY DECAYS AND INHIBITION OF CYTOCHROME OXIDASE IS RELEASED THROUGH THE OXIDATIVE ROUTE OF FORMATION OF PEROXYNITRITE, THE PRODUCT OF THE REACTION OF NO AND SUPEROXIDE RADICAL. THE OVERALL MECHANISM IS LIKELY A METABOLIC PATHWAY COMMON TO MANY PHYSIOLOGICAL PURPOSES EMERGING FROM THE EXISTENCE OF DIFFERENT NITRIC OXIDE SYNTHASE ISOFORMS.

Introduction: The Regulation of Mitochondrial Respiration

During evolution, first bacteria and then eukaryotic cells and multicellular organisms utilized molecular oxygen (O_2). Most of O_2 was taken up first by membranes and then by mitochondria, small intracellular organelles characterized by a high degree of metabolic and genetic autonomy. The reduction of molecular oxygen to water in mitochondria is coupled to the phosphorylation of ADP to ATP, the useful form of energy for cells.

The mitochondrial steady-state O_2 concentration in highly evolved mammals is sustained by a convenient O_2 gradient provided by convective mechanisms such as the cardiorespiratory system. On the basis of capillarity, cell shape and

size, and O_2 diffusion, the intracellular pO_2 may differ considerably from one to another tissue (Gayeski and Honig, 1991). The affinity of mitochondrial respiration for O_2 is known to be very high, but its actual value, and consequently the role of intracellular pO_2 in the regulation of mitochondrial function, is a matter of controversy. The reaction of reduced cytochrome oxidase, the oxygen acceptor and terminal enzyme of the mitochondrial respiratory chain, with O_2 is very fast ($k = 10^8 M^{-1} s^{-1}$, Greenwood and Gibson, 1967). The rate of electron transfer to cytochrome oxidase by the electron transfer chain is the key factor to define the operational O_2 concentration for a half-maximal rate of O_2 uptake, $K_{0.5}$, sometimes called K_{mO_2} (Boveris *et al.*, 1999). The intracellular oxygen concentration in mammalian tissues, which is in the 5–25 μM O_2 range, is close to and

partially overlaps the critical concentration, which is in the 2–6 μM O_2 range, that limits the rate of mitochondrial respiration (Costa *et al.*, 1997).

The tissue pO_2 necessary to maintain high rates of mitochondrial respiration is a subject of interest, mainly within the framework of controversies about the control of mitochondrial respiration by O_2 , and about whether mitochondrial function is O_2 limited in the tissues under physiological conditions. It has been claimed that maximal rates of respiration could be maintained at very low O_2 levels (Gayeski and Honig, 1991; Wittenberg and Wittenberg, 1989), with the relevant $K_{0.5}$ values being between 0.02 and 0.3 μM O_2 in experiments with isolated mitochondria (de Groot *et al.*, 1985; Sugano *et al.*, 1974). On the basis of this high affinity of mitochondrial respiration for O_2 , the rates at which mitochondria perform oxidative phosphorylation were supposed to be rather independent of prevailing pO_2 . The oxidative phosphorylation rates drop only below 0.8 μM O_2 (Weibel and Hoppeler, 1991); therefore, O_2 control of respiration was considered to be important only under severe hypoxia. However, more recent evidence obtained by high-resolution respirometry indicates $K_{0.5}$ values of 0.25–0.30 μM O_2 for state 4 mitochondria and 1.45–1.69 μM O_2 for state 3 mitochondria (Boveris *et al.*, 1999; Costa *et al.*, 1997). The relatively high value of $K_{0.5}$ for state 3 mitochondria is close enough to the physiological O_2 concentration to assume a critical dependence of mitochondrial respiration on tissue pO_2 , understanding that the critical pO_2 , by strict application of Michaelis–Menten kinetics, is the one that will limit mitochondrial O_2 uptake below 80% of the maximal rate.

The Paradigm of “All or Nothing” for Oxygen Uptake and Energy Supply

Since the pioneering work of Chance and others (Chance and Williams, 1955, 1956; Estabrook, 1967; Lardy and Wellman, 1952), it has been thought that the main regulation of O_2 uptake was provided by ADP availability. In the absence of ADP, but with excess substrate and O_2 , isolated mitochondria take up O_2 at a relatively slow rate. The mitochondrial metabolic state, named resting state or state 4, depends on the proton permeability and energy leaks of the inner membrane of the isolated mitochondria. The physiological relevance of O_2 uptake, which may be close to useless, in this metabolic state for cell physiology is under debate. After addition of ADP, and in the presence of excess substrate and O_2 , there is a rapid transition to the maximal physiological rate of respiration and ATP synthesis. In the active metabolic state or state 3, O_2 uptake increased by 5- to 10-fold, and ADP is converted to ATP at maximal speed by reacting with P_i in the phosphorylating ATPase system. State 3 respiration is understood to represent the physiological O_2 uptake that yields energy useful for cell function. The ratio of the rates of O_2 uptake in state 3 and/or state 4 respiration, or respiratory control ratios, as well as the P/O (the ratio of moles of ADP phosphorylated to total O consumed) are sensitive parameters to assess the coupling between

the redox and the energy-conserving reactions in isolated mitochondria.

The interaction of ADP with mitochondrial ATPase or a high $[\text{ATP}]/[\text{ADP}]$ ratio represents a feedback signal (Senior, 1988) consistent with a “simple and elegant model of respiratory control” (Heineman and Balaban, 1990). The net respiratory rate (state 3 minus state 4 oxygen uptake) after a pulse of ADP stimulation follows a hyperbolic relationship with ADP concentration, with $[\text{ADP}]_{0.5}$, the ADP concentration to induce a half-maximal respiratory rate, being 30 and 52 μM for liver and heart mitochondria, respectively (Boveris *et al.*, 1999). The initial concept for kinetic control of respiration by ADP availability (Chance and Williams, 1956; LaNoue *et al.*, 1986) has been reconsidered on the basis of taking as rate-limiting steps the ADP translocation from cytosol to mitochondria or the reduction of electron transfer intermediates in equilibrium with the external phosphorylation potential ($[\text{ADP}] + [\text{P}_i]/[\text{ATP}]$). Moreover, ^{31}P nuclear magnetic resonance (NMR) spectrometry failed to demonstrate significant changes in $[\text{ADP}]$ or $[\text{P}_i]$ in the working heart (Clarke and Willis, 1987; Hassinen *et al.*, 1981), where it was determined that ADP concentration would have to increase by fivefold to sustain a threefold increase in myocardial respiration from resting to active respiration.

In addition, the redox state of the couple NADH/NAD as the regulatory coenzyme of mitochondrial dehydrogenases and cytosolic $[\text{Ca}^{2+}]$, in its double role as a universal dehydrogenase activator and as a cation able to discharge mitochondrial membrane potential, has been considered to play different roles in the regulation of O_2 metabolism. Nevertheless, the intramitochondrial concentration of reduction equivalents always appear very high when derived from dehydrogenase activity, but a dependence *in vivo* of cellular and mitochondrial O_2 uptake on substrate availability and mitochondrial redox state seems likely. In the “all or nothing” paradigm, mitochondrial O_2 uptake and the coupled ATP-producing reactions operate at maximal efficiency and rates over a wide range of O_2 concentrations that certainly include physiological conditions. Both O_2 uptake and energy production cease almost simultaneously in reaching anoxia or state 5. Considering the all or nothing paradigm, the rate of O_2 uptake of perfused rat organs (2.4 μmol $\text{O}_2/\text{min/g}$ liver and 3.6 μmol $\text{O}_2/\text{min/g}$ heart), and the tissue O_2 concentrations (about 20 μM in the liver and 6 μM in the heart), it can be estimated that the transition between normoxia and anoxia will be a rapid and abrupt phenomenon with a time course of 0.5 s in the liver and 0.1 s in the heart. Then, the absence of cellular and mitochondrial regulatory mechanisms for O_2 uptake will leave organelles and cells under an absolute dependence on tissue O_2 supply without a response time to adjust for sudden anoxia.

The Renaissance of Inorganic Nitric Oxide as a Compound of Great Biological Significance

Since 1987 (Ignarro *et al.*, 1987; Palmer *et al.*, 1987), studies on nitric oxide (NO) have characterized this small,

amphipathic nitrogen radical as an important physiological and pharmacological mediator (Bredt and Snyder, 1994; Lowenstein *et al.*, 1994). It is noteworthy that bacteria, which share a close genomic homology with mitochondria, include the synthesis and degradation of NO in the electron transfer process of nitrification–denitrification. Accordingly, the presence of NO oxidoreductases in species such as *Paracoccus denitrificans* was confirmed by the release of NO after exposure of bacteria to nitrites (Goretski *et al.*, 1990). A few years ago, a provocative question was whether mitochondrial electron transfer membranes had some relic pathways keeping the biochemical machinery involving utilization or production of NO. The answer to this question appears to be yes, after the identification of mitochondrial NO synthase (mtNOS) (Ghafourifar and Richter, 1997; Giulivi *et al.*, 1998; Tatoyan and Giulivi, 1998).

The Modulation of Cytochrome Oxidase Activity and Mitochondrial Oxygen Uptake by NO: The O₂–NO Competition

Different groups of investigators have recognized that NO inhibits mitochondrial respiration reversibly and dose dependently (Cleeter *et al.*, 1994; Brown and Cooper, 1994; Okada *et al.*, 1996; Poderoso *et al.*, 1996). This effect was observed in organelles from different tissues containing cyanide-sensitive cytochrome oxidase, whereas it was absent in cyanide-insensitive plant oxidases (Millar and Day, 1996). Formerly, the cytotoxic effects of activated macrophages on tumor cells or bacteria (Adams and Hamilton, 1984; Steinman and North, 1986) were thought to be due to inhibitory NO effects on iron–sulfur compounds and to iron loss at complexes I–II of the respiratory chain. Nevertheless, although NO is now considered a multisite inhibitor of electron transfer, the most impressive effects are related to the inhibition of cytochrome oxidase (complex IV) and to additional reactions involving the intermediates of complex III.

Nitric oxide, with estimated steady-state concentrations in mammalian tissues in the 0.02–0.1 μM range (Knowles *et al.*, 1990; Poderoso *et al.*, 1998), has been recognized as a high-affinity inhibitor of cytochrome oxidase, acting in competition with oxygen (Boveris *et al.*, 1999; Cleeter *et al.*, 1994; Koivisto *et al.*, 1997). The NO concentrations that produce a half-inhibition of cytochrome oxidase activity or O₂ uptake in isolated mitochondria are low, in the range of 80–200 nM. The effect was described in mitochondria and submitochondrial particles from rat gastrocnemius muscle (Cleeter *et al.*, 1994), rat liver (Takehara *et al.*, 1995), rat heart (Borutait'e and Brown, 1996; Cassina and Radi, 1996; Poderoso *et al.*, 1996), and brown fat (Koivisto *et al.*, 1997), in tissue preparations such as rat brain synaptosomes (Brown and Cooper, 1994), in skeletal muscle slices (Shen *et al.*, 1995), and in the isolated rat heart (Poderoso *et al.*, 1998). In addition, the observed increase in whole-body O₂ uptake in the conscious dog after the administration of NOS inhibitors (Shen *et al.*, 1994) is consistent with the NO inhibition of respiration observed in tissues and subcellular preparations.

The effects of NO supplementation on the cytochrome oxidase activity of rat heart submitochondrial particles, O₂ uptake of rat liver mitochondria, and O₂ uptake of perfused rat heart are shown in Fig. 1. Very low NO concentrations, in the 0.10–0.15 μM range, are capable of inhibiting cytochrome oxidase or O₂ uptake in mitochondrial preparations by 50%. The addition of NO to mitochondria produces an inhibition of O₂ uptake and a decrease in membrane potential, the latter detected by rhodamine fluorescence (Takehara *et al.*, 1995). The half-maximal effect of NO on membrane potential is observed in liver mitochondria at about 0.25 μM NO, and it is clearly a less sensitive indicator of NO effects than O₂ uptake as mentioned before.

The inhibition of O₂ uptake is also observed in perfused organs, where the steady-state intracellular NO concentration reached on infusion depends on the NO concentration in the infusion fluid, perfusate flow, NO tissue uptake, and

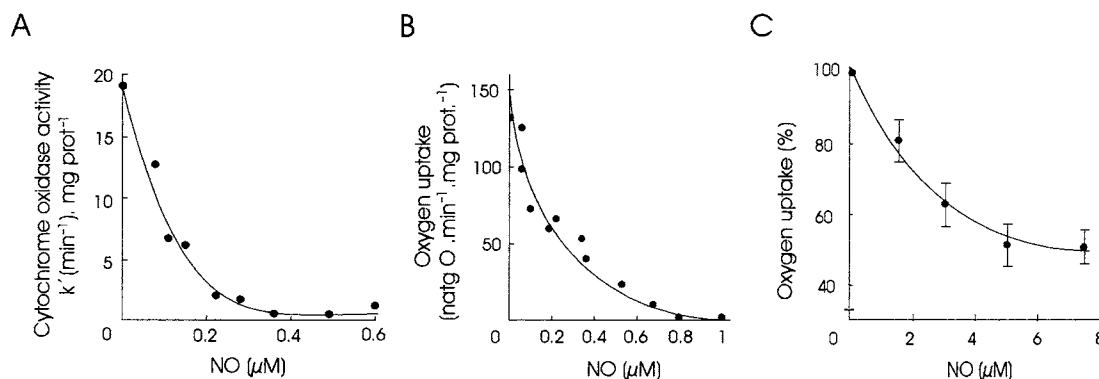

Figure 1 Inhibitory effects of nitric oxide on cytochrome oxidase activity of rat heart submitochondrial particles (A), on the state 3 oxygen uptake of rat liver mitochondria (B), and on the oxygen uptake of isolated and perfused beating rat heart (C). In C, the NO concentration in the solution infused into the rat heart coronary circulation is given in the abscissa. When NO was infused at a rate of 2 $\mu\text{M}/\text{min}$ the calculated tissue NO concentration was 0.2 μM . Hence, NO-dependent 50% inhibition of oxygen uptake was comparable to the data in A and B.

NO binding to cellular and mitochondrial components such as myoglobin (Mb) and cytochrome oxidase. These two hemoproteins react with NO with great affinity, with nearly diffusion-limited rate constants ($k \approx 10^8\text{--}10^9\text{ M}^{-1}\text{ s}^{-1}$; Shen *et al.*, 1995). The presence of Mb significantly shortens the half-life of NO in the perfused heart and decreases NO steady-state concentration (Konorev *et al.*, 1996). In the NO-perfused heart, the tissue metmyoglobin (metMb) levels depend on NO infusion levels as shown by tissue spectral studies (Poderoso *et al.*, 1998). It is likely that, under physiological conditions, the main part of NO generated by endothelial NOS reacts with MbO₂, and a remnant NO diffuses to mitochondria. The diffusion process is analogous to that of oxygen, where O₂-Mb and O₂-cytochrome oxidase are the two complexes involved in O₂ transport to mitochondria (Kennedy and Jones, 1986). The reactivity of MbO₂ with NO and the metmyoglobin reductase activity of muscle tissue keep, by means of a sort of buffer action, the cellular and mitochondrial concentration of NO in a low, nontoxic range with a minimal effect on cytochrome oxidase activity. In this setting, muscle steady-state NO concentrations can be considered as equal to the NO concentration measured by diffusion equilibrium in the perfusate or in the expanded intracellular space, namely, 20 nM NO in rat diaphragm (Boczkowski *et al.*, 1999) and 100 nM in perfused heart after bradykinin stimulation (Poderoso *et al.*, 1998). These NO concentrations are similar to those that effectively inhibit cytochrome oxidase (Fig. 1).

The biological effect of a given NO concentration will depend on the simultaneous O₂ concentration; lowering the pO₂ increases and extends the effects of NO (Takehara *et al.*, 1996; Cassina and Radi, 1996). A series of reports indicated a competition between O₂ and NO for cytochrome oxidase reaction centers (Boveris *et al.*, 1999; Brown, 1995; Cassina and Radi, 1996; Zhang *et al.*, 1996). The inhibition of O₂ uptake by NO in isolated rat liver and heart mitochondria is consistent with an affinity of NO for cytochrome oxidase that is 150 times higher than the corresponding O₂ affinity (Boveris *et al.*, 1999). Similar O₂/NO competition ratios of 400–500 have been reported for rat brain synaptosomes (Brown and Cooper, 1994) and ratios of 500–1000 for brown fat mitochondria (Koivisto *et al.*, 1997). This point is of physiological interest because O₂ concentrations in myocardial cells have been reported as low as 3 to 8 μM O₂ (Gayeski and Honig, 1991), a condition in which a NO steady-state concentration of 50 nM would effectively compete with O₂, producing a cytochrome oxidase inhibition of about 30%. Detailed studies on the interactions of NO with the binuclear center of cytochrome oxidase are available (Torres *et al.*, 1995). In addition, some authors proposed that cytochrome oxidase may reduce NO to N₂O (Zhao *et al.*, 1995), whereas others were unable to observe such reducing activity (Stubauer *et al.*, 1998).

The inhibitory effects of NO on cytochrome oxidase activity and oxygen metabolism have been considered as a regulatory and adaptative physiological mechanism in response to changes in O₂ availability (Poderoso *et al.*, 1996,

1998). The effects have also been implicated in inflammatory, neurodegenerative, or ischemic diseases (Brown, 1997). To some extent, the two roles could be just two views of the same reversible effects of NO on cytochrome oxidase and of the role of NO in the generation of peroxynitrite (ONOO⁻). Both effects arise from the ability of NO to react with superoxide anion (O₂⁻), producing ONOO⁻. The utilization of NO by the reaction of NO with O₂⁻ determines the intramitochondrial NO steady-state concentrations and the O₂:NO ratio that regulates cytochrome oxidase activity. Production of the powerful oxidant ONOO⁻ is easily linked to mitochondrial and cellular toxic effects (Xie *et al.*, 1998; Boczkowski *et al.*, 1999). In this way, pathophysiology or toxicity depends on the amplification of a normal control pathway based on the intramitochondrial NO steady-state concentrations.

The Mitochondrial Production of Oxygen Active Species

Superoxide anion (O₂⁻) and hydrogen peroxide (H₂O₂) are reactive oxygen species normally produced as by-products of mitochondrial respiration and as products of cytosolic and peroxisomal enzyme activities involving the univalent and bivalent reduction of oxygen. The discovery of superoxide dismutase (SOD) by McCord and Fridovich (1969) and its ubiquitous distribution in aerobic tissues indicated that O₂⁻ was a normal metabolite in mammalian cells (Fridovich, 1978). Moreover, it was observed that both O₂⁻ and H₂O₂ are produced in mitochondria and in the cytosol in specific ways. Accordingly, Mn-SOD and Cu,Zn-SOD are strictly localized in the mitochondrial and cytosolic compartments, respectively. The concentration of O₂⁻ is similar in mitochondria and in bacteria ($\sim 10^{-10}\text{ M}$) (Boveris and Cadenas, 1997; Imlay and Fridovich, 1991), and it is higher than in the cytosol, where it is about 10^{-11} M . The production of noncharged H₂O₂ by stoichiometric dismutation of O₂⁻ occurs in both compartments catalyzed by both SOD types with diffusion-limited rate reactions ($k = 1.9\text{--}2.3 \times 10^9\text{ M}^{-1}\text{ s}^{-1}$). Hydrogen peroxide can diffuse freely outside mitochondria and is partially utilized by glutathione peroxidase, and by peroxisomal catalase.

The production of O₂⁻ in mitochondria is a process that encompasses electron transfer and enzyme activities inherent to mitochondrial function and is considered a normal consequence of aerobic metabolism. In fact, diversion of electrons to reduce O₂ by one-electron transfer can be considered as a thermodynamically favored and kinetically unfavored process of the redox steady states of the components of the mitochondrial respiratory chain. Some intermediates such as ubisemiquinone and the flavin semiquinone of NADH dehydrogenase are kinetically able to undergo collisional and noncatalyzed reactions with one-electron transfer to the O₂ molecule (Boveris and Cadenas, 1997). In the past, before the utilization of NO, the mitochondrial production of O₂⁻

was measured in submitochondrial particles devoid of superoxide dismutase and supplemented with nonphysiological compounds, such as antimycin or myxothiazol (Cadenas and Boveris, 1980).

The Mitochondrial Production of Superoxide Radical Is Stimulated by Nitric Oxide

The exposure of mitochondria or submitochondrial particles to NO initiates or markedly increases the mitochondrial production of both O_2^- and H_2O_2 (Poderoso *et al.*, 1996; Packer *et al.*, 1996). In the presence of 0.2–1 μM NO, mitochondria isolated from almost all rat tissues have NO-dependent H_2O_2 production rates of 0.05 to 0.2 nmol/min/mg protein.

The dependence of the rate of H_2O_2 production in rat liver mitochondria on NO concentration is shown in Fig. 2A; addition of NO has a marked effect that saturates the mitochondrial respiratory chain at about 0.7 μM NO, also reported as an inhibition of succinate–cytochrome *c* reductase activity (Poderoso *et al.*, 1996). The observed effect appears to express the reactions of (a) ubisemiquinone formation by the direct nonenzymatic reaction of UQH_2 with NO and $ONOO^-$ (Poderoso *et al.*, 1999a), (b) ubisemiquinone autooxidation to yield O_2^- , and (c) formation of H_2O_2 from O_2^- .

The amperometric determination of NO in a suspension of submitochondrial particles supplemented with the NO donor DETA-NO results in a model of NO steady-state levels in the mitochondrial matrix. The continuous release of NO by the donor provides a constant, quasi-equilibrium NO concentration that mimics the maintenance of an intramitochondrial NO steady-state concentration by the continuous NO production from mtNOS (Giulivi, 1998). Considering the inside-out topology of the submitochondrial particles in which the M side of the mitochondrial inner membrane is exposed to the reaction medium and the electrode, the conditions of the experiment in Fig. 2B afford a model of the

intramitochondrial matrix space. With such view, the NO electrode is monitoring an expanded mitochondrial matrix. The NO-generating system was able to keep a constant steady-state level of about 0.5 μM NO. The addition of succinate initiated active production of O_2^- in the already NO-supplemented mitochondrial membranes that decreased, through $ONOO^-$ formation, the steady-state concentration of NO to about 0.2 μM . Addition of superoxide dismutase, which nearly eliminates O_2^- from the reaction mixture, restored the NO level to the initial values. Thus, the O_2^- and NO produced by the inner mitochondrial membrane are vectorially released into the matrix, where the steady-state levels of both are determined by the very fast reaction of $ONOO^-$ formation. This fast reaction is a classic free radical termination reaction in which two species with unpaired electrons react at diffusion-controlled rates ($k = 1.9 \times 10^{10} M^{-1} s^{-1}$) (Koppenol, 1998). The increased production of mitochondrial H_2O_2 under NO influence was also observed in the isolated beating rat heart, where H_2O_2 was released in the cardiac effluent depending on the infused NO concentration (Poderoso *et al.*, 1998).

The mechanistic basis for the NO-induced formation of intramitochondrial O_2^- and $ONOO^-$ include three cooperative actions: (a) NO inhibits the electron transfer chain in complex III at the cytochromes *b-c*₁ region (Poderoso *et al.*, 1996, 1998), increasing the levels of ubisemiquinone which on autooxidation reduces O_2 to O_2^- ; (b) NO inhibits cytochrome oxidase and increases the reduction levels of the components of the electron transfer chain, including ubiquinol and ubisemiquinone, on the substrate side of cytochrome oxidase; and (c) NO reacts directly with ubiquinol to produce nitroxyl anion (NO^-) and ubisemiquinone (Poderoso *et al.*, 1999a, 1999b). The occurrence of the latter reaction is illustrated in Fig. 3 with the use of ubiquinol-0 (UQ_0H_2). The rate of NO utilization after addition of ubiquinol, the formation of the semiquinone intermediate, and the spectral changes indicating the oxidation of the quinol to quinone by NO are shown in Fig. 3A–C, respectively. The one-electron transfer reaction of ubiquinol to NO has a rate

Figure 2 Nitric oxide increases H_2O_2 production in liver submitochondrial particles in the presence of succinate (A). The addition of succinate to liver submitochondrial particles decreases the NO steady-state concentration of the reaction medium that was released by 0.5 mM DETA-NO, and the effect is completely reversed by 2 μM SOD (B).

Figure 3 The NO-induced cohort of reactions leading to increased mitochondrial production of O_2^- and its dismutation product H_2O_2 are initiated by the reaction of NO with membrane ubiquinol, as shown in model reactions. A sensitive NO electrode shows the increased decay rate of a $0.7 \mu M$ NO pulse after addition of $10 \mu M$ UQ_0H_2 in anaerobiosis *in vitro*, at pH 5.5 (A). The reaction produces a ubisemiquinone intermediate detected by electron paramagnetic resonance (EPR) (amplitude 1 G, 50 kHz) (B). The ubisemiquinone on autoxidation forms O_2^- , and finally, as followed by UV spectral changes (C), the consecutive reactions oxidize UQH_2 (a) to UQ (b). Modified from *Free Radical Biology and Medicine* vol. 26, Poderoso *et al.*, "The reaction of nitric oxide with ubiquinol," p. 925; copyright 1999, with permission from Elsevier Science.

constant of 10^3 – 10^4 (Poderoso *et al.*, 1999a, 1999b); nitroxyl anion (NO^-) is a reactive intermediate that forms nitrous oxide (N_2O) as a stable end product. It has been reported that the reaction of NO with mitochondrial cytochrome *c* also produces NO^- (Sharpe and Cooper, 1998). Hence, the reactions of NO with components or products of the mitochondrial respiratory chain are, as in bacteria, reductive and yield NO^- , or they are oxidative and yield $ONOO^-$.

The Rate of Mitochondrial NO Utilization

The rate of mitochondrial NO utilization can be determined through the amperometric monitoring of NO pulses added to mitochondria and submitochondrial particles (Poderoso *et al.*, 1999b). In this way, the time course of NO decay after the addition of $0.4 \mu M$ NO pulses to rat liver submito-

chondrial particles under different experimental conditions were monitored to characterize the routes and rates of mitochondrial NO metabolism (Fig. 4A). In anaerobic conditions, NO was utilized at a rate of about 0.12 nmol/min/mg protein. It is apparent that under the assayed conditions, some reduced components of the mitochondrial respiratory chain, likely ubiquinol, cytochrome *c*, and cytochrome oxidase, are able to reduce NO to NO^- . In aerobic conditions, the NO pulses were utilized following first-order processes with rates of NO metabolism that linearly depended on NO concentrations in the range of 0.025 – $0.40 \mu M$ NO. The rate of NO utilization corresponding to a maximal concentration of $0.2 \mu M$ NO, in the physiological NO range, and in the presence of succinate as mitochondrial reductant, was $1.0 \text{ nmol NO/min/mg}$ protein (Fig. 4B). Submitochondrial particles supplemented with $2 \mu M$ ubiquinone (UQ_0) to expand the ubiquinol pool showed an increased rate of NO utiliza-

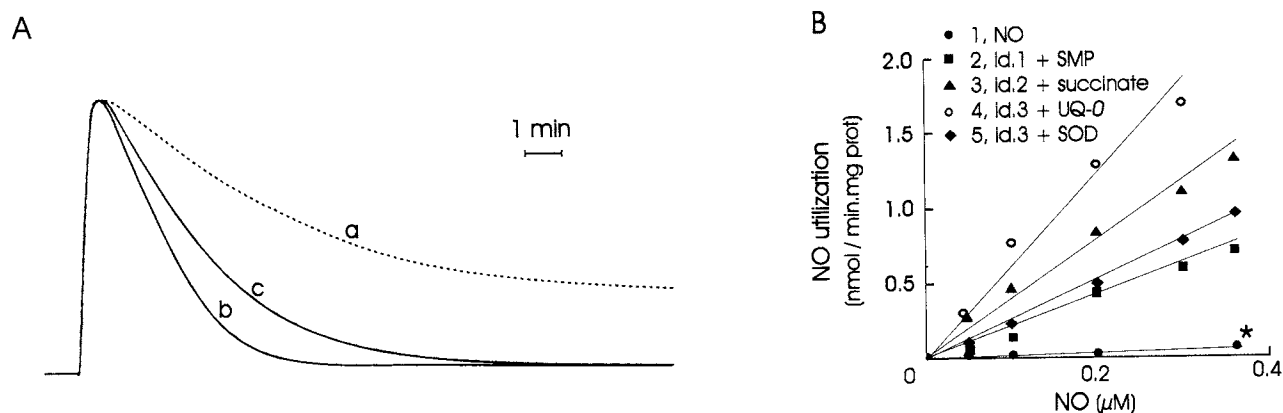

Figure 4 NO decays in the presence of submitochondrial particles and 6 mM succinate in anaerobiosis (trace a), in aerobiosis at $220 \mu M$ O_2 (trace b), and in aerobiosis at $220 \mu M$ O_2 plus $2 \mu M$ SOD (trace c) (A). The NO decay rates at physiological NO concentration (0 – $0.4 \mu M$) follow first-order kinetics for NO (B). *, units are in $\mu M \text{ min}^{-1}$. Figure 5 The NO decay rate in liver mitochondria is linearly dependent on mitochondrial protein content (A). Both H_2O_2 production and NO decay rates depend on reduced ubiquinone incorporated into liver submitochondrial particles, previously depleted by extraction with cyclopentane and lyophilized, in the presence of 6 mM succinate and 2 μM myxothiazol (B). Adapted from (Poderoso *et al.*, 1999b), *Journal of Biological Chemistry*, with permission.

tion, 1.3 nmol NO/min/mg protein, that was inhibitable by the addition of superoxide dismutase (Poderoso *et al.*, 1999b). As previously described (Richter, 1997; Boczkowski *et al.*, 1999), these effects are consistent with the reaction of NO and O_2^- to yield ONOO^- as the main route of NO utilization by mitochondria under aerobic conditions.

Ubiquinone Supplementation, Superoxide Production, NO Decay, and Cytochrome Oxidase Inhibition

Both the soluble and the membrane-bound quinones that are reduced by the mitochondrial respiratory chain produce, by autooxidation, O_2^- , the stoichiometric precursor of H_2O_2 (Cadenas *et al.*, 1977). Acetone-extracted and ubiquinone-supplemented submitochondrial particles showed rates of H_2O_2 production and of NO utilization that are linearly dependent on the content of membrane-bound and substrate-reducible ubiquinone-10 (UQ_{10}) (Fig. 5), as was previously described for H_2O_2 production (Boveris and Chance, 1973; Boveris *et al.*, 1976). Similarly, rat liver submitochondrial particles supplemented with exogenous soluble ubiquinones, such as UQ_0 and UQ_2 , showed up to 10 times higher H_2O_2 production (Poderoso *et al.*, 1999b). In this setting, NO decay rates appeared well correlated with the rates of O_2^- generation in the ubiquinol-supplemented mitochondrial preparations. These results acquire more relevance when it is considered that the experiments were done at constant $[\text{O}_2]$, that oxygen uptake was unaffected by ubiquinone depletion (except at the lowest levels), and that other components of the electron transfer system were not essentially modified. The rate constant for the ubiquinol/NO reaction is about $0.5 \times 10^4 \text{ M}^{-1} \text{ s}^{-1}$ at pH 6.0, with ubiquinol-10 (UQH_2) (Poderoso *et al.*,

1999a), and $2.1 \times 10^3 \text{ M}^{-1} \text{ s}^{-1}$ at pH 7.4, with UQ_9H_2 in the rat liver mitochondrial membranes (Poderoso *et al.*, 1999b).

The cytochrome oxidase activity of rat liver submitochondrial particles supplemented with NO exhibited a lag phase or inhibition time before enzyme activity starts. The NO inhibition time of cytochrome oxidase activity was strongly decreased either by addition of soluble ubiquinones to the reaction medium or by supplementation with membrane-bound ubiquinone in acetone-extracted mitochondrial membranes; a decrease to one-half of the inhibition time was observed at about 15 nmol/mg protein of UQ_{10} (Fig. 6).

Figure 6 The time of inhibition of cytochrome oxidase activity by NO is decreased by increasing the succinate reducible ubiquinone (UQ_{10}) in cyclopentane-extracted and UQ_{10} -supplemented rat liver mitochondrial membranes. Adapted from (Poderoso *et al.*, 1999b), *Journal of Biological Chemistry*, with permission.

The Dual Effect of NO on Mitochondrial Hydrogen Peroxide Production

A biphasic effect is observed when the dependence of the rate of mitochondrial H_2O_2 production on NO concentration is examined in the 0–20 μM NO range (Fig. 7). In the first phase, in the 0–3 μM range, a marked increase in the rate of H_2O_2 was observed, as described before and shown in Fig. 2A. At higher NO concentrations, in the 3–20 μM range, a second phase was observed in which there was a decrease of H_2O_2 production on increasing NO concentration. The biphasic nature of the NO effect on mitochondrial production of O_2^- and H_2O_2 was also recognized when submitochondrial particles added with succinate and 5,5-dimethyl-1-pyrroline *N*-oxide (DMPO) were analyzed by electron paramagnetic resonance (EPR). At 5 μM NO, the formation of a DMPO– H_2O_2 adduct was detected by a characteristic six-line spectrum that was inhibited by catalase; however, at 20 μM NO the adduct was not formed (Fig. 7). In the second phase, at high NO levels, formation of ONOO^- precluded the reaction of O_2^- with DMPO, which evolves to DMPO– H_2O_2 after the formation of a DMPO– O_2^- adduct.

Peroxynitrite-Dependent Production of Superoxide Radical

The addition of relatively low concentrations of 0.25–2 μM ONOO^- to rat heart submitochondrial particles supplemented with myxothiazol and succinate elicited production of O_2^- , which was consistent with an oxidation of the

Figure 7 Dual effect of NO on mitochondrial production of H_2O_2 in mitochondria in the presence of succinate. The production of hydrogen peroxide increases up to a plateau at about 5 μM NO and afterward progressively decreases due to formation of ONOO^- . After addition of succinate and DMPO, the DMPO– H_2O_2 adducts are detected by EPR only at the lower NO concentrations (5 μM NO) and not at higher NO concentrations (20 μM NO).

Figure 8 Peroxynitrite induces the production of O_2^- in heart mitochondrial membranes.

membrane-bound ubiquinol to the corresponding ubisemiquinone and its subsequent autooxidation, yielding O_2^- (Fig. 8). The process yield was about 0.5 O_2^- produced per ONOO^- added. An additional indication of the reactivity of ONOO^- toward ubiquinol was indirectly observed when the steady-state concentration of NO was amperometrically followed in submitochondrial particles in the presence of a DETA–NO system that continuously generates NO (as shown in Fig. 2B). Uric acid, which in these conditions behaves as a specific ONOO^- scavenger, prevents almost totally the succinate effect, indicating a role of ONOO^- as reactant in O_2^- production. The reaction of ubiquinol with ONOO^- ($k = 4.8 \times 10^2 \text{ M}^{-1} \text{ s}^{-1}$) eliminates a powerful oxidant of the mitochondrial matrix and completes the metabolic pathway of mitochondrial NO. This reaction constitutes an extra source of O_2^- to eliminate NO. On the other hand, at relatively high NO concentrations, the continuous formation and exposure of mitochondrial matrix components to ONOO^- will produce protein nitration and nitrosylation, leading to alterations that lead to enzyme inactivation and alterations in energy-linked functions (Lizasoain *et al.*, 1996; Szabó *et al.*, 1996; Xie *et al.*, 1998).

The NO-Induced Mitochondrial Production of Superoxide Anion Regulates NO Metabolism, Cytochrome Oxidase Activity, and Oxygen Uptake

The rich biochemistry of NO has a key role in the regulation of cell oxygen uptake and energy production. This highly diffusible small molecule has dual effects on tissue respiration. On the one hand, NO generated by endothelial NOS produces dilation of the small blood vessels; by lengthening the equilibration time between oxygenated hemoglobin (HbO_2) in the blood and tissue pO_2 , this NO generation favors oxygen delivery and uptake by the tissues. On the

other hand, it reversibly inhibits cytochrome oxidase activity and cell oxygen uptake, which allows O_2 molecules to further diffuse in the tissue and decreases the steepness of the oxygen gradient in the tissue near the area of the normoxia/anoxia transition. The degree of cytochrome oxidase inhibition by NO depends on the simultaneous pO_2 , a fact that enhances the physiological NO effects at low pO_2 . Apparently, NO and O_2 compete for a binding site at the binuclear center formed by cytochrome a_3^{2+} and Cu_B^+ of cytochrome oxidase. Then, the inhibition of mitochondrial respiration by NO can be expressed as a function of the ratio $[O_2]/[NO]$. As was discussed previously, values of 150, 400–500, and 500–1000 (Boveris *et al.*, 1999) have been reported for this ratio to produce half-maximal inhibition of mitochondrial respiration.

Nitric oxide also inhibits mitochondrial electron transfer at the ubiquinol–cytochrome *b* region of the respiratory chain, blocking succinate–cytochrome *c* reductase activity with increased reduction of cytochrome *b* (Poderoso *et al.*, 1996) and increased rates of O_2^- production in submitochondrial particles and of H_2O_2 in mitochondria. The interaction of NO with the NO-reactive component of the ubiquinol–cytochrome *b* area of the mitochondrial respiratory chain is also reversible but is not affected by the $[O_2]:[NO]$ ratio. The NO-dependent mitochondrial production of O_2^- provides a regulatory mechanism to remove NO and the reversible inhibition of cytochrome oxidase. An increasing NO concentration will sequentially inhibit cytochrome oxidase activity and electron transfer in the ubiquinone–cytochrome *b* region of the mitochondrial respiratory chain. The increased O_2^- production and steady-state concentration will in turn set a feedback mechanism by clearing NO through the Beckman reaction ($O_2^- + NO \rightarrow ONOO^-$) (Beckman, 1990). In that sense, as was previously described, the use of ubiquinone-supplemented mitochondrial preparations provides clear evidence that the increased rates of O_2^- production are associated with faster removal of the NO-induced cytochrome oxidase inhibition.

The active NO synthase located in the inner membrane of rat liver mitochondria (mtNOS) is able to produce NO at rates of 2–3 nmol/min/mg protein, rates that are about two times higher than the inner membrane production of O_2^- (Giulivi *et al.*, 1998). The enzyme uses L-arginine (K_m 5–7 μM) and is activated by Ca^{2+} ; the activity is better measured in submitochondrial particles, toluene-permeabilized mitochondria, or broken mitochondria. It has been shown that the addition of the NOS inhibitor N^G -L-monomethyl-L-arginine to respiring mitochondria increases oxygen uptake by 10–15%, which indicates that NO produced by mtNOS is able to regulate mitochondrial O_2 uptake. The normal mitochondrial NO steady-state concentration can be estimated to be about 30 nM; it has been calculated as 50 nM in rat liver on the basis of maximal mtNOS activity (Giulivi, 1998), measured as 20 nM NO in isolated rat diaphragm (Boczwaski *et al.*, 1999) and measured as 100 nM in perfused rat heart stimulated by bradykinin (Poderoso *et al.*, 1998). The sequential effects of bradykinin on myocardial O_2 uptake, NO

Figure 9 Oxygen uptake (black bars), NO release (gray bars), and H_2O_2 release (white bars) in normal and bradykinin-stimulated isolated perfused rat heart.

release, and production of oxygen active species are self-explanatory with respect to the regulatory mechanisms of oxygen metabolism (Fig. 9).

An understanding of the biological signaling by which NO regulates mitochondrial oxygen uptake and energy supply requires a knowledge of the metabolic routes of mitochondrial NO (Fig. 10). For the following analysis only mitochondrial NO utilization was considered, disregarding the sink effect of the fast reactions of NO with muscle cytosolic myoglobin and blood hemoglobin that certainly will have an effect on mitochondrial and cellular NO steady-state concentrations.

The selective permeability of the inner mitochondrial membrane makes the mitochondrial matrix space a differentiated intracellular compartment. The key features involving NO and O_2^- metabolism are the impermeability of the inner membrane to O_2^- and H^+ , the relative impermeability of the same membrane to $ONOO^-$, and the presence of Mn-SOD at a level that is about five times lower than in the cytosol. The reactions of O_2^- with NO [reaction (I), $k = 1.9 \times 10^{10} M^{-1} s^{-1}$] and with Mn-SOD [reaction (II), $k_2 = 2.4 \times 10^9 M^{-1} s^{-1}$] are apparently the only ones that occur in the mitochondrial matrix at rates that effectively contribute to O_2^- utilization.

Figure 10 Oxidative and reductive NO reactions in mitochondria that contribute to keep NO steady-state levels and the regulation of oxygen metabolism.

Alternative chemical reactions [reactions (I) and (II)] yield differential equations [Eq. (1) and (2)], where [SOD] indicates total SOD concentration ($[\text{SOD}^+] + [\text{SOD}^{2+}]$). The combined expression in equation (3) is obtained after considering the common factor $[\text{O}_2^-]$, and it indicates the ratio of production of ONOO^- and H_2O_2 via the two alternative reactions of O_2^- utilization.

$$-d[\text{NO}]/dt = -d[\text{O}_2^-]/dt = d[\text{ONOO}^-]/dt = k_1[\text{NO}][\text{O}_2^-] \quad (1)$$

$$-d[\text{O}_2^-]/dt = 0.5d[\text{H}_2\text{O}_2]/dt = k_2[\text{O}_2^-][\text{SOD}] \quad (2)$$

$$(d[\text{ONOO}^-]/dt)/(d[\text{H}_2\text{O}_2]/dt) = k_1[\text{NO}]/0.5k_2[\text{O}_2^-][\text{SOD}] \quad (3)$$

It can be calculated that for physiological conditions, considering intramitochondrial Mn-SOD as $\approx 3 \mu\text{M}$ (Boveris and Cadenas, 1997) and intramitochondrial $[\text{NO}]$ as 50 nM , that the intramitochondrial production of ONOO^- will account for 15% of O_2^- utilization, with the remaining 85% yielding H_2O_2 as final product (Poderoso *et al.*, 1999b). Under conditions of inducible NOS (iNOS) activation, intramitochondrial NO may reach 100 nM (Poderoso *et al.*, 1998), and consequently ONOO^- formation may account for as much as 28% of O_2^- utilization. Finally, in the setting of induction of iNOS, cell and intramitochondrial NO may reach $0.5 \mu\text{M}$ NO with very high production rates of ONOO^- that could account for more than 50% of O_2^- utilization. Besides the oxidative pathway of reaction (I), intramitochondrial NO will be metabolized through reductive one-electron transfer reactions from cytochrome oxidase [reaction (III)] and from UQH_2 [reaction (IV)].

The rate of reaction (I) under physiological conditions will be, according to equation (1) and after taking $[\text{O}_2^-]$ as 10^{-10} M , about 90 nM s^{-1} . The rate of reaction (III) is, according to our data on the metabolism of NO pulses by rat liver submitochondrial particles in the presence of cyanide, about $0.1 \text{ nmol NO/min/mg protein}$. The process can be understood as a secondary pathway of cytochrome oxidase activity with a slow first-order decay of $\text{Cyt } a_3^{2+}\text{-NO}$ ($k_6 = 0.13 \text{ s}^{-1}$) (Giuffrè *et al.*, 1996). With $18 \mu\text{M}$ cytochrome oxidase in the liver and assuming that 10% of the enzyme is in the form of the oxidase-NO complex, the rate of NO utilization will be about 6 nM s^{-1} . However, the mechanism of this reaction, postulated on the basis of the inhibition by cyanide of NO utilization (Zhao *et al.*, 1995), has not been confirmed in other studies with purified cytochrome oxidase (Stubauer *et al.*, 1998), but a reduction of NO by cytochrome *c*, the reductant of cytochrome oxidase, was reported (Sharpe and

Cooper, 1998). The rate of reaction (IV) can be, after considering UQH_2 content in the rat liver and a value of k_7 of $2.1 \times 10^3 \text{ M}^{-1} \text{ s}^{-1}$, about 30 nM s^{-1} .

In summary, the considered rates seem to indicate that in rat liver mitochondria, NO is metabolized about 70% through the oxidative formation of ONOO^- , about 5% through the reduction by cytochrome oxidase and cytochrome *c*, and about 20–30% through reduction by ubiquinol, in the latter two cases yielding NO^- . The rate of NO oxidation by O_2 in the tissues to yield NO_2 is considered negligible, considering the quadratic dependence on $[\text{O}_2]$ and the low tissue pO_2 . At $25 \mu\text{M}$ O_2 in the liver, utilization of $1 \mu\text{M}$ NO by this reaction will take 35 hours. Peroxynitrite, a strong oxidant with $E^\circ = 1.13 \text{ V}$, appears to be produced in the mitochondrial matrix at the rate of 90 nM s^{-1} , as discussed before. The reaction of ONOO^- with ubiquinol yields ubisemiquinone [reaction (V); $k = 4.8 \times 10^2 \text{ M}^{-1} \text{ s}^{-1}$], which produces O_2^- by autooxidation [reaction (VI); $k = 8 \times 10^3 \text{ M}^{-1} \text{ s}^{-1}$] and subsequently, by dismutation, H_2O_2 . The whole series of reactions transforms the powerful oxidant ONOO^- into the less reactive and diffusible H_2O_2 .

Two biological roles are played by the two reduced forms of ubiquinone: the fully reduced ubiquinol acts as an antioxidant clearing ONOO^- [reaction (V)], and the univalently reduced ubisemiquinone acts as a prooxidant by the generation of O_2^- radical [reaction (VI)].

The fine regulation of the steady-state concentration of NO in the mitochondrial matrix, accomplished by its reactions with O_2^- , cytochrome oxidase, and ubiquinol, does regulate cytochrome oxidase activity. Knowledge of the intracellular or intramitochondrial signaling that activates mtNOS is essential to fully understand the overall process.

The Different NOS Isoforms and the Utility of Regulating Mitochondrial O_2 Uptake

On the basis of the previous considerations, it is reasonable to speculate about the role of the different NOS isoforms and the NO regulation of mitochondrial and cellular O_2 uptake (Fig. 11). The widespread distribution of NOS I in the nervous system and skeletal muscle (Kobzik *et al.*, 1994) may lead, through an inhibition of mitochondrial O_2 uptake and a reduction of ATP availability for the Na^+, K^+ -ATPase membrane pumps, to transient decreases in the resting potential of the synaptic terminals and neural fibers. The physiological action will be a facilitation of neural excitability and synaptic transmission, with effects on muscle contractility.

The regulation of O_2 metabolism in connection with transient decreases in tissue O_2 availability during circulatory changes is consistent with activity of endothelial NOS. Ischemia, hypoxia, “shear” stress, and microcirculatory and rheological alterations should stimulate eNOS activity and

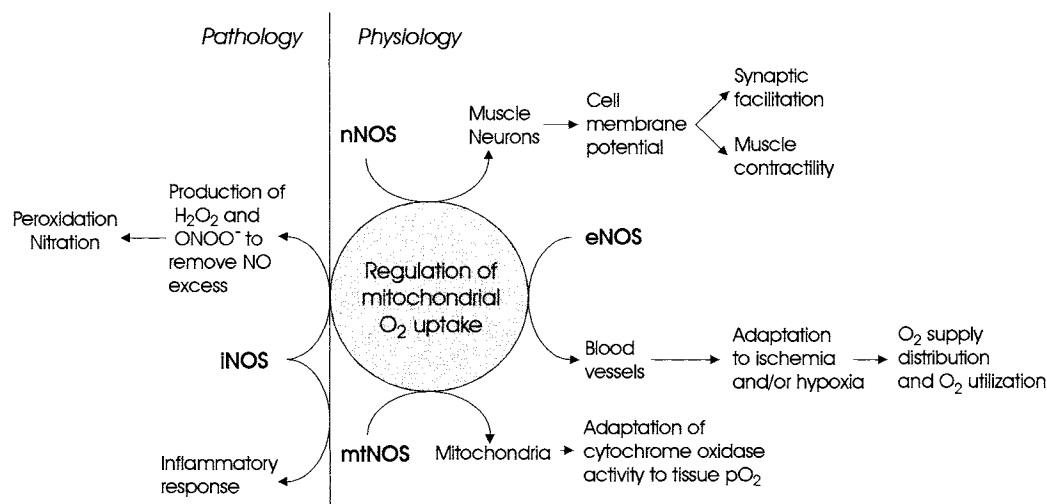

Figure 11 General and tissue-specific effects of the NO inhibition of oxygen uptake related to NOS isoforms in physiological and pathological settings.

release of NO (K_m of eNOS for O₂ is low, about 16 μM), which will diffuse into adjacent cells to inhibit cytochrome oxidase. On the basis of O₂/NO competition, cytochrome oxidase activity and O₂ uptake adapted to the O₂ supply, which allows O₂ to diffuse further along its gradient and lowers the steepness of the pO₂ gradient in the normoxic–anoxic transition (Fig. 12). A more general metabolic action should be expected from mtNOS (NOS IV) (Giulivi, 1998), which is likely related to continuous regulation of the specific activity of cytochrome oxidase to tissue pO₂. In this way, if arginine is available, mitochondrial O₂ uptake should

not follow the “all or nothing” paradigm, but it should be exactly adjusted to O₂ concentrations. Evidence provided by Koivisto *et al.* (1997) and by Giulivi (1998) indicates that the rate of mitochondrial O₂ uptake depends on NO concentration in the range of physiological pO₂. Knowledge of the O₂ dependence of mitochondrial NO production, in other words, the K_m for O₂ of mtNOS, is essential to the understanding of the NO regulation of mitochondrial respiration. The pathological dependence of O₂ uptake on O₂ availability in sepsis and septic shock (Bihari *et al.*, 1987; Danek *et al.*, 1980; Poderoso *et al.*, 1994) may be due to increased NO

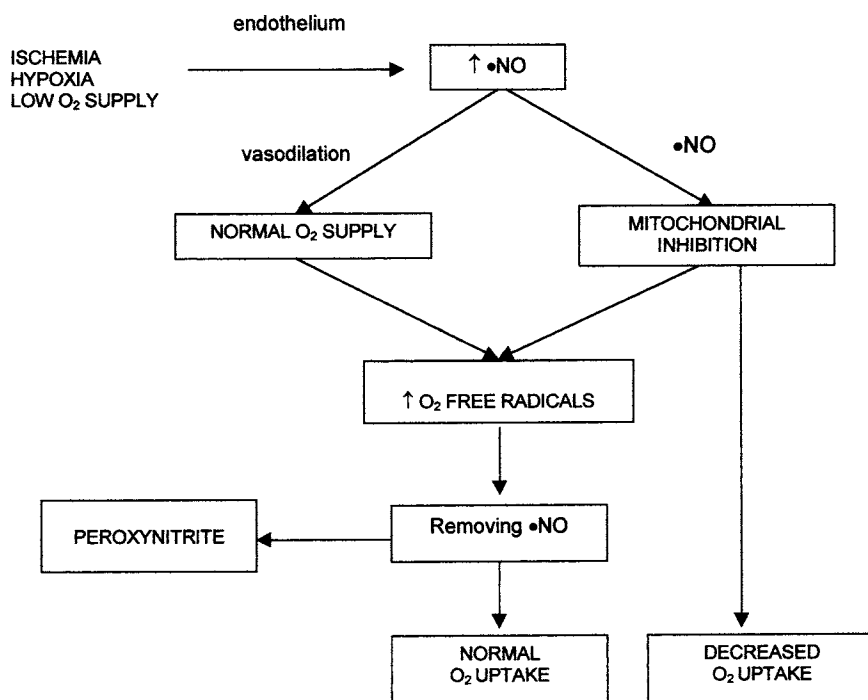

Figure 12 The interplay of nitric oxide and O₂ free radicals in the modulation of O₂ uptake. Reproduced from (Poderoso *et al.*, 199b), *Archives of Biochemistry and Biophysics*, with permission.

steady-state concentrations in the whole body owing to iNOS expression in macrophages and other immunocompetent NO-producing cells, a fact that dangerously amplifies the underlying regulatory mechanism.

Summary

Oxygen metabolism has been considered to follow a paradigm in which oxygen uptake does not change with respect to oxygen supply, up to critical hypoxic conditions. This behavior was thought to be dependent on the great affinity of mitochondrial cytochrome oxidase for oxygen. However, the discovery of nitric oxide led to the observation that this radical may modulate oxygen uptake by reacting with cytochrome oxidase with an even greater affinity than oxygen. Considering that, in terms of steady-state concentrations, there is an O₂–NO competition, cytochrome oxidase activity and oxygen uptake in the presence of NO should be dependent on, rather than independent of, O₂ levels. In this way, the modulation of mitochondrial NO concentration should be critical with respect to the regulation of oxygen metabolism.

The routes for NO metabolism include oxidative and reductive pathways. Accordingly, mitochondrial superoxide anion is produced by the oxidation of membrane ubiquinol by NO. In this way, and under physiological conditions, most of the NO decay and, consequently, the inhibitory effects of NO on cytochrome oxidase are modulated by the NO/O₂^{•−} reaction leading to the formation of peroxynitrite. From this perspective, active oxygen species should not be merely toxic end products of oxygen metabolism; they can also modulate NO levels and O₂ uptake. In contrast, a pathological amplification of this process becomes potentially dangerous because of increasing peroxynitrite steady-state concentrations. The regulatory NO effect on oxygen metabolism may be related to specific and general purposes in connection with the presence of different NOS isoforms, including the mitochondrial one.

Structure–Function Relationships in NO-Sensitive Guanylyl Cyclase

D. Koesling and A. Friebe

*Institut für Pharmakologie und Toxikologie
Ruhr-Universität Bochum
Bochum, Germany*

ALTHOUGH RESEARCH IN THE NITRIC OXIDE (NO) FIELD HAS EXPANDED CONSIDERABLY, OUR KNOWLEDGE ABOUT THE NO RECEPTOR, SOLUBLE GUANYLYL CYCLASE, HAS GROWN ONLY SLOWLY. DESPITE THE IDENTIFICATION OF FOUR SUBUNITS (α_1 , α_2 , β_1 , β_2) AT THE DNA LEVEL, SO FAR ONLY TWO HETERODIMERIC ISOFORMS OF THE ENZYME ($\alpha_1\beta_1$, $\alpha_2\beta_1$) HAVE BEEN SHOWN TO OCCUR AT THE PROTEIN LEVEL. HOWEVER, NO FUNCTIONAL DIFFERENCES AMONG THE ISOFORMS HAVE BEEN FOUND, AND THE PHYSIOLOGICAL RELEVANCE OF TWO SIMILARLY REGULATED ISOFORMS REMAINS UNCLEAR.

THE CLOSE STRUCTURAL RELATIONSHIP OF SOLUBLE GUANYLYL CYCLASE TO THE MEMBRANE-BOUND GUANYLYL CYCLASES AND ADENYLYL CYCLASES, INITIALLY SUGGESTED BY THE HIGH DEGREE OF HOMOLOGY, HAS BEEN SUPPORTED BY FUNCTIONAL DATA. THE CRYSTAL STRUCTURE OF THE CATALYTIC CENTER OF ADENYLYL CYCLASES PROVIDES A MODEL OF THE CATALYTIC CENTER OF SOLUBLE GUANYLYL CYCLASE.

MORE PRECISE UNDERSTANDING OF THE REGULATION OF SOLUBLE GUANYLYL CYCLASE BY NO, ESPECIALLY CONCERNING THE ACCEPTOR SITE FOR NO (I.E., THE PROSTHETIC HEME GROUP), AND THE MECHANISM OF ACTIVATION HAVE BEEN OBTAINED. A NEW COMPOUND, YC-1, UNVEILED A NOVEL MECHANISM OF SENSITIZATION OF SOLUBLE GUANYLYL CYCLASE TOWARD NO AND CO, WHICH MAY HAVE BROAD PHARMACOLOGICAL AND EVEN PHYSIOLOGICAL IMPLICATIONS. ENDOGENOUS LIGANDS AT THE YC-1 BINDING SITE MAY EXIST, OR POST-TRANSLATIONAL MODIFICATIONS AT THIS YC-1 EFFECTOR SITE MAY OCCUR, THAT BY ADJUSTING THE NO SENSITIVITY OF THE ENZYME, ARE CAPABLE OF MODULATING NO/CGMP SIGNALING.

Introduction

Soluble guanylyl cyclase (sGC) acts as the receptor molecule for nitric oxide (NO), thereby mediating most effects of NO in its function as a signaling molecule (Fig. 1). The enzyme contains a prosthetic heme group which serves as a receptor for NO; after binding of NO to the heme group of the enzyme, the catalytic activity, that is, the conversion of

guanosine triphosphate (GTP) to guanosine cyclic monophosphate (cGMP), is stimulated up to 200-fold. Cyclic GMP, as an intracellular messenger, can act on three different effector molecules, namely, cGMP-dependent protein kinases, cGMP-gated ion channels, and cGMP-regulated phosphodiesterases. Hence, the effects of cGMP depend on the expression of a specific cGMP receptor protein in a given cell type. For example, cGMP-dependent kinases have been

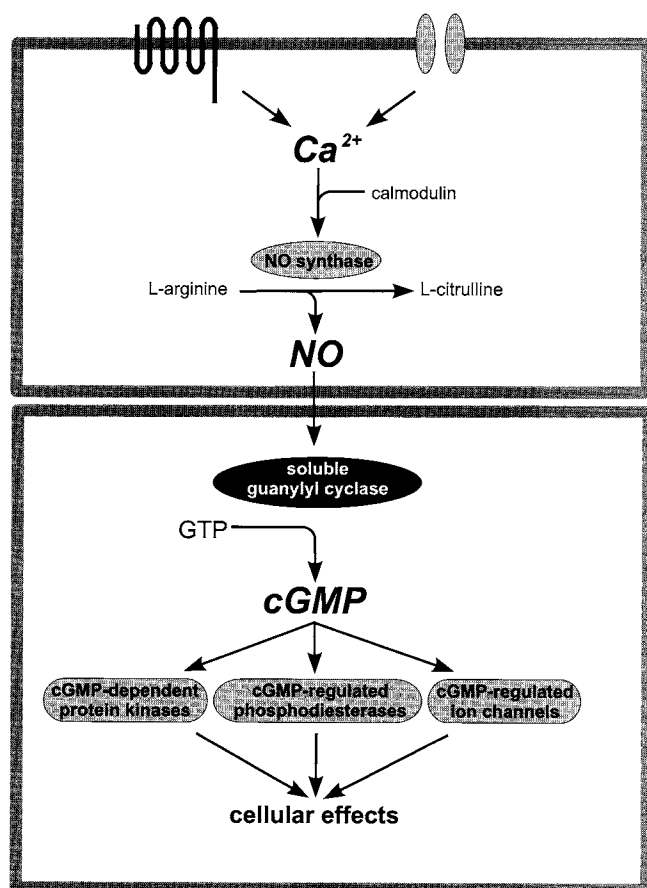

Figure 1 The NO–cGMP signaling cascade. Neuronal and endothelial NO synthases are regulated by the intracellular calcium concentration, with a rise of the calcium concentration leading to activation and NO formation. NO can diffuse into neighboring cells and stimulate soluble guanylyl cyclase, the enzyme that catalyzes the conversion of GTP to cGMP. Cyclic GMP alters the activity of the cGMP receptor molecules (cGMP-dependent protein kinases, cGMP-regulated phosphodiesterases, cGMP-regulated ion channels), finally leading to changes in cellular function.

reported to decrease the intracellular calcium concentration, whereas opening of cGMP-gated cation channels is known to increase the intracellular calcium concentration. Important NO/cGMP-mediated cellular effects include smooth muscle relaxation, modulation of synaptic transmission, and inhibition of platelet aggregation (for review, see Schmidt and Walter, 1994, and Moncada and Higgs, 1995).

Besides the soluble, that is, cytosolic GCs, membrane-bound forms of guanylyl cyclases (mGCs) exist (Fig. 2). Because these GCs are not stimulated by NO, they will not be extensively discussed in this chapter (for review, see Wedel and Garbers, 1997). Membrane-bound GCs belong to the group of receptor-linked enzymes with one membrane-spanning domain. The N-terminal extracellular parts of the different isoforms are quite diverse and form the ligand-binding domains, whereas the highly conserved intracellular C-terminal domains possess the catalytic activity. Several isoforms of mGCs (GC-A to GC-F) have been identified. Owing to the diversity of the ligand-binding domains, vari-

ous isoforms of mGCs (GC-A, GC-B, GC-C) are stimulated by different peptide hormones; GC-A, for example, is stimulated by the natriuretic peptides ANP and BNP, whereas GC-B exhibits the highest affinity for the C-type natriuretic peptide. Physiologically, GC-C is activated by the intestinal peptide hormone guanylin, whereas under pathophysiological conditions stimulation of GC-C by the heat-stable enterotoxin of *Escherichia coli* results in diarrhea. As expected, the catalytic domains of all cGMP-forming isoforms, namely, soluble and membrane-bound guanylyl cyclases, are closely related and, in addition, show similarity to the catalytic domains of the cAMP-forming adenylyl cyclases (see Fig. 2).

This chapter gives a short overview on NO-sensitive sGC with special emphasis on structural features of the enzyme. This chapter first introduces the isoforms, the general structure, and the functional domains of the subunits. In the second part of the chapter, the different stimulators of sGC are presented, and their structural implications are discussed.

Structure of Soluble Guanylyl Cyclase

Soluble Guanylyl Cyclase Isoforms and General Properties

Soluble GC has been purified by several groups. All isolation procedures yielded an enzyme with two subunits termed α_1 and β_1 , with molecular masses of 73 and 70 kDa, respectively (Gerzer *et al.*, 1981b; Humbert *et al.*, 1990; Stone and Marletta, 1994). The purified enzyme was shown to contain heme as a prosthetic group (Gerzer *et al.*, 1981a) and was stimulated up to 200-fold by NO. Specific activities of 25 to 40 $\mu\text{mol cGMP min}^{-1} \text{mg}^{-1}$ have been reported under NO-stimulated conditions (Stone and Marletta, 1995; Russwurm *et al.*, 1998). Another isoform ($\alpha_2\beta_1$) of sGC has been shown to occur in placenta. This isoform very likely exists in other tissues as well; so far, it is not clear why the different purification procedures never yielded this isoform. Although there are considerable differences between the α subunits, the $\alpha_2\beta_1$ heterodimer purified from Sf9 cells exhibited the same specific activity and level of stimulation by NO as the $\alpha_1\beta_1$ heterodimer. In addition, both isoforms showed comparable behavior toward the new modulators YC-1 and 1*H*-[1,2,4]oxadiazolo[4,3-*a*]-quinoxalin-1-one (ODQ). Both sGC isoforms, similar to other nucleotide-converting enzymes, require divalent metal ions as cofactors for catalysis. Besides Mg^{2+} , the enzymes can utilize Mn^{2+} , with catalytic activities under nonstimulated conditions being about fourfold higher in the presence of Mn^{2+} . However, NO-stimulated enzyme catalytic rates are lower in the presence of Mn^{2+} than in the presence of Mg^{2+} . Under nonstimulated conditions, both sGC isoforms exhibit K_m values of approximately 100 and 10 μM for MgGTP and MnGTP as substrate, respectively. Under NO-stimulated conditions, the K_m values are approximately 10 μM in the presence of either metal ion.

Figure 2 Schematic representation of the structures of guanylyl cyclases and adenylyl cyclases. Shown are the known heterodimers of soluble guanylyl cyclase ($\alpha_1\beta_1$, $\alpha_2\beta_1$), a representative membrane-bound guanylyl cyclase with different ligands at the respective receptor domain, and a representative adenylyl cyclase. The dimerization partner of the β_2 subunit of guanylyl cyclase has not been identified yet. The catalytic domains are symbolized by light gray triangles on the membrane-bound GC, the β subunit of sGC, and, correspondingly, the C2 domain of AC. The dark shaded triangles correspond to the cyclase catalytic domain in the α subunits of sGC and the C1 domain of AC. ANP, natriuretic peptide type A; BNP, natriuretic peptide type B; CNP, natriuretic peptide type C.

Subunits of Soluble Guanylyl Cyclase

Both the α_1 and β_1 subunits of the enzyme purified from lung have been cloned and sequenced. Expression experiments revealed that both subunits are required to form a catalytically active enzyme (Harteneck *et al.*, 1990; Buechler *et al.*, 1991). In lung, brain, and kidney, comparably high mRNA levels for the α_1 and β_1 subunits have been found (Nakane *et al.*, 1990).

The two other sGC subunits, α_2 and β_2 , have been found by homology screening (Yuen *et al.*, 1990; Harteneck *et al.*, 1991). The so-called α_3 and β_3 subunits of sGC (Giulli *et al.*, 1992) represent human variants of the α_1 and β_1 subunits; changes in the reading frame account for the differences in amino acid sequences (Zabel *et al.*, 1998). It is noteworthy that the β_2 subunit contains 86 additional amino acids including an isoprenylation consensus sequence (-CVVL) at the C terminus. Thus, the β_2 subunit may be attached to the membrane, and, indeed, the expressed β_2 subunit can be detected in membrane fractions. However, although there is one report on the formation of an active $\alpha_1\beta_2$ heterodimer (Gupta *et al.*, 1997), the role of the β_2 subunit is unclear. Most laboratories have been unable to form a β_2 -containing cGMP-synthesizing dimer with any of the known α or β subunits. Furthermore, the physiological occurrence of the β_2 subunit at the protein level has not been demonstrated. In contrast to β_2 , the α_2 subunit is able to substitute for the α_1 subunit, as shown by the formation of a catalytically active, NO-sensitive heterodimer on coexpression with the β_1 subunit (Harteneck *et al.*, 1991). In human placenta, the natural

occurrence of the α_2 subunit has been demonstrated, and here the β_1 subunit has been identified as its physiological dimerization partner (Russwurm *et al.*, 1998). Comparison of both heterodimers ($\alpha_1\beta_1$, $\alpha_2\beta_1$) did not reveal any differences between the isoforms with respect to the heme content, NO sensitivity, kinetic properties, and the responsiveness toward modulators (see also section on sGC isoforms). Taking into consideration that the N-terminal thirds of the α subunits share only 27% identical amino acids, this lack of differences between the isoforms is surprising. Right now, the physiological relevance of the two similarly regulated isoforms cannot be explained.

Functional Domains

As previously outlined, four subunits of sGC (α_1 , α_2 , β_1 , β_2) have been identified so far (see Fig. 2). Comparison of the primary structures of all known subunits shows that they can be divided into three distinct domains: an N-terminal region, a central part, and a C-terminal cyclase catalytic domain (Fig. 3).

In comparison to the central and catalytic part of the subunits, the N-terminal regions differ considerably. For example, only 27% identical amino acids are shared by the otherwise highly conserved α_1 and α_2 subunits. Despite these differences in primary structure, either α subunit coexpressed with the β_1 subunit yields enzymes with similar properties (see earlier), indicating that most of the regulatory features of sGC are determined by the β_1 subunit. Within the

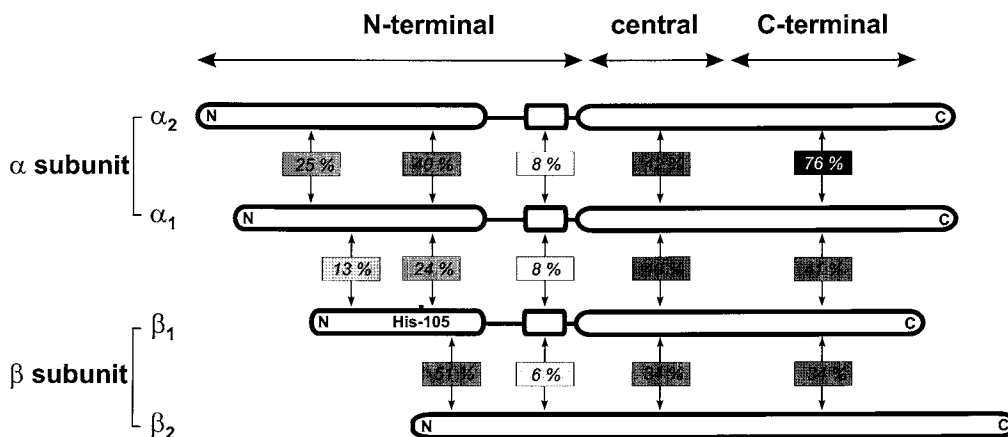

Figure 3 Comparison of the primary structure of the subunits of sGC. The polypeptide chains are shown as white bars, and gaps are indicated by a black line. The numbers between the subunits indicate the amount of identical amino acids shared between the respective subunits in a certain region. The C termini of the subunits of sGC are unrelated. The position of the His-105 as the heme-coordinating residue of the β_1 subunit is given. The regions chosen for comparison are as follows: amino acids 1–161 of α_2 , 1–126 of α_1 , and 1–56 of β_1 subunits; 162–268 of α_2 , 127–234 of α_1 , 57–164 of α_2 , and 1–101 of β_2 subunits; 269–321 of α_2 , 235–282 of α_1 , 165–212 of β_1 , and 102–208 of β_2 subunits; 322–483 of α_2 , 283–441 of α_1 , 213–383 of β_1 , and 205–368 of β_2 subunits; 484–698 of α_2 , 442–660 of α_1 , 384–605 of β_1 , and 369–581 of β_2 subunits.

N-terminal regions, there is a stretch of about 100 amino acids that shows a higher degree of conservation among the α subunits or the β subunits than between α and β . Conceivably, these regions define the properties of an α or a β subunit. In accordance with that, histidine-105 of the β_1 subunit (see later), which acts as the proximal ligand of the heme group, is located within this region.

The central regions of the subunits of sGC show a high degree of homology. Most likely, these regions are involved in the dimerization of the subunits, as has been shown for the respective parts of the membrane-bound enzymes (Wilson and Chinkers, 1995). Obviously, dimerization itself does not require two different sGC subunits as there is a report of catalytically inactive $\alpha_1\alpha_1$ or $\beta_1\beta_1$ homodimers (Zabel *et al.*, 1999).

The catalytic C-terminal domains of sGC reveal the highest degree of homology. These domains are also very similar to the respective regions in the membrane-bound guanylyl cyclases and in the adenylyl cyclases (see also section on the catalytic domain). With the help of deletion mutants of either of the three cyclic nucleotide-forming enzymes, these domains have been clearly shown to be sufficient to carry out the catalytic reaction. In all cases, association of two catalytic domains was required for the formation of the cyclic nucleotide.

In general, the results obtained with the N-terminally or C-terminally truncated subunits show that the regulatory and catalytic properties of sGC can indeed be attributed to the N-terminal and C-terminal region of the subunits, respectively. The regulatory and catalytic modules are able to work independently of each other, and at least the catalytic domain can be controlled by other regulatory modules, as

shown by the receptor-linked guanylyl cyclases or the G-protein-stimulated AC.

THE REGULATORY HEME-BINDING DOMAIN

The N-terminal parts of the subunits of sGC are responsible for heme binding. The heme content of the enzyme has been a matter of debate. Whereas most groups found up to 1 mole of heme per mole of heterodimer (Gerzer *et al.*, 1981a; Humbert *et al.*, 1990; Tomita *et al.*, 1997b), the group of Marletta reported a heme content of 1.5 mole of heme per mole of heterodimer (Stone and Marletta, 1995). However, the latter results were obviously due to an incorrect protein determination, and more recent results obtained by the same group are consistent with a heme to heterodimer ratio of 1:1 (Denninger and Marletta, 1999).

Experiments with truncated subunits showed that the N termini of the α_1 and β_1 subunits are required for proper heme binding, although the two subunits appear to contribute unequally (Foerster *et al.*, 1996). Obviously, the β_1 subunit plays a more important role in heme binding, as it is required for NO stimulation, whereas the N terminus of the α_1 subunit is essential for a normal heme-binding capacity (Foerster *et al.*, 1996). For heme binding, the N terminus of α_1 can also be substituted with the N terminus of the β_1 subunit, as shown by Zhao and Marletta (1997). They demonstrated that the N-terminal half of the β_1 subunit (amino acids 1–385), expressed in *E. coli*, is able to form dimers. These homodimers were shown to be capable of binding heme, resulting in a heme–protein complex with characteristics similar to those of the wild-type enzyme. The exclusive role of the N-terminal region of the β_1 subunit in heme binding is underlined by point mutations of conserved cysteines

(Friebe *et al.*, 1997). These mutations cause a loss of the heme group when performed in the β_1 subunit; mutations of the corresponding cysteines in the α_1 subunit do not alter NO responsiveness.

The heme group of sGC exhibits an absorption maximum at 431 nm, indicative of a histidine as the axial ligand. Using site-directed mutagenesis, histidine-105 of the β_1 subunit has been identified as the axial ligand of the heme group (Wedel *et al.*, 1995; Zhao *et al.*, 1998). Since the mutant lacking histidine-105 remained insensitive to NO even after heme reconstitution, histidine-105 may very likely be required to transduce the NO-induced, heme-mediated activation within the protein.

Although clearly representing a functional domain, the heme binding region appears to be in close association with the catalytic domain, as GTP was shown to induce an increase in NO dissociation from the heme group and to lead to a change of the Raman spectra of NO–sGC (Kharitonov *et al.*, 1997; Tomita *et al.*, 1997a).

CATALYTIC DOMAIN

The C-terminal catalytic domains of the subunits of sGC are also conserved in the membrane-bound GCs and the adenylyl cyclases (ACs). ACs are integral membrane proteins with two hydrophobic domains and two cytosolic domains (see Fig. 2). Each of the hydrophobic domains contains six supposed transmembrane helices. The two cytosolic domains, termed C1 and C2, are homologous to each other and are homologous to the catalytic domains of both soluble and membrane-bound GCs (Sunahara *et al.*, 1996). Like sGC, ACs contain two different but conserved catalytic domains. In the adenylyl cyclases, both domains are located on one

molecule, whereas in sGC, each of the two subunits contributes one catalytic domain. Comparison of the primary structures of the catalytic domains of adenylyl cyclases and sGC suggests that the catalytic domains of the α and β subunits correspond to the C1 and C2 domains of the adenylyl cyclases, respectively. This assumption has been very elegantly verified experimentally by Sunahara *et al.* (1998), who turned sGC into a cAMP-producing enzyme by exchanging the three amino acids responsible for the nucleotide specificity (see later).

A tremendous advance in the cyclase research has been the determination of the crystal structure of the catalytic core of the ACs. The analysis of the crystal structure showed that the catalytic center of AC consists of the homologous C₁ and C₂ domains arranged in a head-to-tail fashion. The interface between the C₂ and the C₁ domain forms two pseudosymmetric regions; one of these regions comprises the binding site for the substrate MgATP, and the other one, which has probably evolved from a former ATP binding site, binds the activator forskolin (Fig. 4). Based on this structure, the amino acid residues responsible for nucleotide interaction have been identified (Tesmer *et al.*, 1997); indeed, the exchange of the corresponding residues of sGC into the respective amino acids of the ACs resulted in an sGC that produced cAMP in an NO-sensitive manner (Sunahara *et al.*, 1998). These data underline the structural similarity among the ACs and sGCs. It is amazing to learn that the switch from adenylyl cyclase to guanylyl cyclase has also been performed in nature, as shown to be the case for the *Paramecium* guanylyl cyclase, which has the overall structure of an adenylyl cyclase (Linder *et al.*, 1999). The close relationship of ACs and GCs is further demonstrated by a report of a

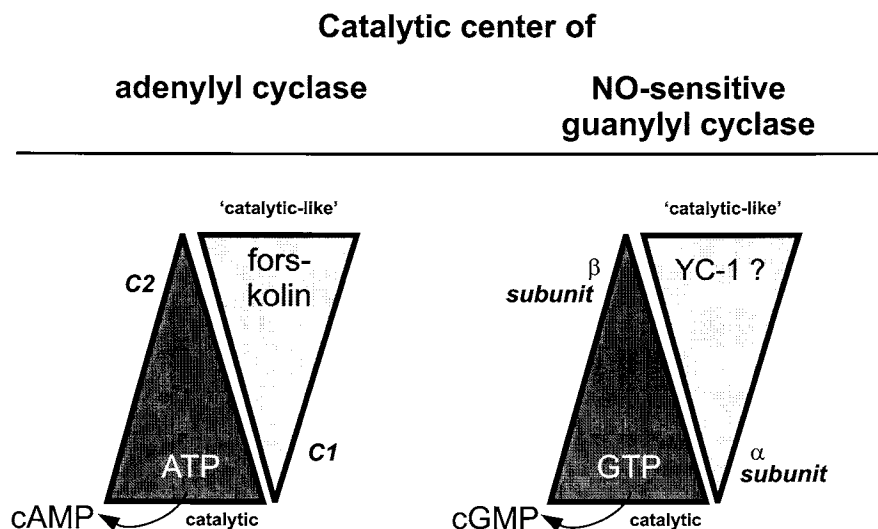

Figure 4 Schematic diagram of the catalytic domains of adenylyl cyclase and soluble guanylyl cyclase. The catalytic regions of heterodimeric AC and sGC are represented as triangles; the C2 domain of AC and the corresponding β subunit of sGC are drawn in dark gray, the C1 and α subunit are light gray. Conversion of ATP to cAMP and of GTP to cGMP are shown for the respective cyclase. The “catalytic-like” domain of the AC binds the diterpene activator forskolin. Although the corresponding ligand for sGC has not been identified, it is tempting to speculate on YC-1 as the possible ligand.

chimeric cyclase (Weitmann *et al.*, 1999) in which the C2 domain of an AC forms a cAMP-synthesizing enzyme with the α_1 subunit of sGC.

In addition to one ATP binding site, a pseudosymmetric region that comprises the binding site for the activator forskolin has been identified. As the effects of forskolin are very similar to those of the sGC activator YC-1 (see section on YC-1), and as the catalytic centers of ACs and GCs are very much alike, one may speculate that, analogous to forskolin, YC-1 binds to the corresponding site in sGC (see Fig. 4). Indeed, mutations within this putative YC-1-binding region led to an almost 10-fold increase in activity under nonstimulated conditions (Friebe *et al.*, 1999). Interestingly, the activity of the mutant was further increased by Mn^{2+} , almost reaching the level of the NO-stimulated wild-type enzyme, whereas NO had very little additional effect. In analogy to the YC-1 effect, the mutated enzyme showed a decreased NO dissociation rate (in the presence of Mg^{2+}). The results with the mutant show that the sGC region corresponding to the forskolin binding site has a profound influence on the catalytic rate and the dissociation of NO and suggest that YC-1 may exert its effects by binding to this site or by changing the conformation at this site. In addition, one may speculate about endogenous ligands or posttranslational modifications at this site that would result in alterations of the catalytic rate or the sensitivity of sGC toward NO.

Regulation of Soluble Guanylyl Cyclase

Nitric Oxide

The cyclic GMP-forming activity of the enzyme sGC was first described in 1969 (Hardman and Sutherland, 1969; Schultz *et al.*, 1969; White and Auerbach, 1969; Ishikawa *et al.*, 1969), and hormones which led to an increase of the intracellular calcium concentration were shown to elevate cGMP levels (Schultz *et al.*, 1973). In the late 1970s, NO-containing compounds were identified as potent activators of sGC (Arnold *et al.*, 1977; Böhme *et al.*, 1978). Despite the stimulatory effect of these NO-containing compounds, the physiological significance of NO-induced activation of the enzyme did not become clear until the identification of endothelium-derived relaxing factor (EDRF) as NO (Palmer *et al.*, 1987; Ignarro *et al.*, 1987). After the discovery of NO in the vascular system, NO formation was reported to occur throughout the body and, subsequently, the enzymes responsible for the synthesis of NO were identified and termed NO synthases. More details about further progress in the NO research are given in other chapters of this book.

Carbon Monoxide, a Physiological Activator of Soluble Guanylyl Cyclase?

The role of carbon monoxide (CO) as an activator of sGC has been a matter of debate. CO was shown to induce effects similar to those evoked by NO. There are reports about a role

of CO in long-term potentiation, in olfactory signal transduction, in vasorelaxation, as well as in inhibition of platelet aggregation (Brüne and Ullrich, 1987; Brüne *et al.*, 1990; Marks *et al.*, 1991; Maines, 1997). A family of enzymes, the heme oxygenases, appears to be most relevant for the production of CO as signaling molecule. These enzymes catalyze the degradation of heme to biliverdin and CO (Maines, 1988), a reaction which appears to be a rather uneconomical way of producing a signaling molecule. In addition, the currently unknown short-term regulation of the heme oxygenases argues against an involvement in signal transduction (Maines, 1997). The proposed role of CO as a physiological stimulator of sGC stands in contrast to its rather poor sGC-stimulating properties (see section on mechanism of activation of sGC). However, in the presence of the substance YC-1 (see also section on modulators of sGC), CO is able to stimulate sGC to nearly the same extent as NO (Friebe *et al.*, 1996a). Although this capability of CO to stimulate sGC similarly to NO is striking, an endogenously occurring substance with YC-1-like properties would be required for CO to act as a physiological activator of sGC. In addition, even in the presence of YC-1, the CO concentrations required for sGC activation are rather high (Russwurm *et al.*, 1998).

Mechanism of Heme-Mediated Activation of Soluble Guanylyl Cyclase

The prosthetic heme group of sGC acts as the acceptor site for NO (Humbert *et al.*, 1990; Stone and Marletta, 1995), and the presence of the heme group has been shown to be required for the stimulatory effect of NO (Craven and DeRubertis, 1978; Ignarro *et al.*, 1982a; Ohlstein *et al.*, 1982). Removal of the heme group abolishes NO-induced activation, and the stimulatory effect of NO is restored on heme reconstitution of the enzyme (Ignarro *et al.*, 1986; Foerster *et al.*, 1996). The heme group is not covalently bound and exhibits an absorbance maximum at 431 nm (Fig. 5). This peak indicates a five-coordinated ferrous heme with a histidine as the axial ligand at the fifth coordinating position (Stone and Marletta, 1994). Using site-directed mutagenesis, His-105 of the β_1 subunit has been identified as the axial ligand (Wedel *et al.*, 1994; Zhau *et al.*, 1998). NO binds to the sixth coordination position of the heme iron and leads to the breakage of the histidine-to-iron bond, yielding a five-coordinated nitrosyl-heme complex with an absorbance maximum at 398 nm. The opening of the histidine-to-iron bond is thought to initiate a conformational change, resulting in the activation of the enzyme.

The finding that protoporphyrin IX, the iron-free precursor of heme, stimulates sGC independently of NO supports this mechanism of activation (Ignarro *et al.*, 1982b). Protoporphyrin IX, a heme lacking the iron, appears to mimic the structure of the NO-heme complex in which the iron is moved out of the plane of the porphyrin ring. Thus, in the protoporphyrin IX- and in the NO-stimulated enzyme, the axial histidine is unbound. On the other hand, breakage of the histidine-to-iron bond is required but does not appear to

Figure 5 Heme as the NO acceptor site of soluble guanylyl cyclase. In the nonactivated state, the heme of sGC is five-coordinated with the histidine-105 of the β_1 subunit bound to the fifth coordination position of the heme iron (absorption maximum at 431 nm). NO binds to the sixth coordination position of the heme iron and leads to breakage of the histidine-to-iron bond so that the fifth coordination position is now free (absorption maximum at 398 nm). Protoporphyrin IX is able to substitute for the heme group and stimulates the enzyme (absorption maximum at 410 nm). Like NO, CO binds to the sixth coordination position of the heme iron, but, in contrast to NO, CO does not lead to the rupture of the histidine-to-iron bond; therefore, CO binding results in a six-coordinated heme (absorption maximum at 423 nm). For further explanation, see text.

be sufficient for activation, as a mutant without the proximal histidine and, accordingly, without the histidine-to-iron bond did not show an increased catalytic rate. These results indicate that the proximal histidine not only coordinates the heme but also is required to mediate the stimulatory process (see the section on the regulatory heme-binding domain).

Like NO, CO has a very high affinity for heme groups, and thus it also binds to the heme group of sGC. In contrast to NO, which activates sGC up to 200-fold, the stimulation by CO only ranges between four- and six-fold (Stone and Marletta, 1994). CO does not lead to breakage of the heme-to-iron bond, as it yields a six-coordinated heme with an absorption maximum at 423 nm in which the heme-to-iron bond remains intact. Therefore, the low stimulatory property of CO is in accordance with the assumption that the breakage of the histidine-to-iron bond is a prerequisite for sGC activation.

It is widely accepted that the association of NO to a five-coordinate heme iron is nearly diffusion-controlled, whereas the dissociation of NO is generally rather slow. Studies on

the dissociation of NO from sGC revealed that the enzyme has a comparably high NO dissociation rate, yielding a half-life of approximately 5 s at 37°C for the NO–sGC complex (Kharitonov *et al.*, 1997). Apparently, it is a unique property of the heme environment in sGC to allow such fast activation. This half-life is sufficient to allow rapid deactivation of the enzyme in biological systems, although it has to be kept in mind that the presence of an NO scavenger is a prerequisite for such fast deactivation.

Redox Regulation of Soluble Guanylyl Cyclase?

When in the early days of research on sGC the physiological activator of the enzyme NO was unknown, a multitude of different activators and regulators of the enzyme were proposed, most of them exhibiting redox-active properties (for review, see Waldman and Murad, 1987). These substances, which do not act by releasing NO (“non-NO activators”), constitute a rather heterogeneous group; thus, several mechanisms of activation have been postulated and

subsumed as “redox regulation” of sGC (Böhme *et al.*, 1984). In contrast to the more than 200-fold stimulation by NO, the stimulatory effect of the substances was only severalfold. Although many of the effects of redox-active compounds have been postulated to be mediated by the cysteine residues of the enzyme (DeRubertis and Craven, 1977; Brandwein *et al.*, 1981; Böhme *et al.*, 1983), point mutation of 15 conserved cysteines impaired neither catalytic activity nor NO stimulation, indicating that the cysteines of sGC are unlikely to be the mediators of this redox regulation (Friebe *et al.*, 1997).

Purified sGC was shown to be sensitive to the small amounts of NO present in the atmosphere (Friebe *et al.*, 1996b). Studies with one of the reported non-NO activators of sGC, superoxide dismutase, revealed that the stimulatory effect is not caused by a direct effect on the enzyme. Rather, superoxide dismutase, which eliminates superoxide (O_2^-), leads to an increase in the concentration of dissolved atmospheric NO in a solution by preventing the inactivation of NO by O_2^- to peroxynitrite (Friebe *et al.*, 1998a). Other non-NO activators of sGC may also exert their action by decreasing the amount of O_2^- and thereby increasing the concentration of NO. Therefore, the redox regulation of sGC may simply be an *in vitro* artifact, arising from the extreme NO sensitivity of sGC and the O_2^- -mediated inactivation of the dissolved atmospheric NO.

Modulators of Soluble Guanylyl Cyclase

ODQ, AN INHIBITOR OF THE STIMULATED ACTIVITY OF SOLUBLE GUANYLYL CYCLASE

Methylene blue and LY-83583 have been used as inhibitors of sGC, although they show very little specificity and, for example, interfere with NO formation and NO release from NO synthases (Mayer *et al.*, 1993). A potent and selective inhibitor of sGC, the quinoxalin derivative 1*H*-[1,2,4]oxadiazolo[4,3-*a*]-quinoxalin-1-one (ODQ), has been identified (Garthwaite *et al.*, 1995). As ODQ was shown not to interfere with NO formation, it appears to represent an ideal tool to discriminate cGMP-dependent and cGMP-independent effects of NO. Originally, ODQ was shown to prevent NO-induced cGMP formation in the brain; now the inhibitory effect of ODQ on sGC has been demonstrated in a variety of other cells and tissues.

Studies with purified sGC revealed that ODQ binds in an NO-competitive manner and leads to an apparently irreversible inhibition of the stimulated enzyme, leaving basal activity almost unchanged. Spectral analysis suggests oxidation of the heme iron as an underlying mechanism of the inhibitory effect of ODQ (Schrammel *et al.*, 1996). The notion that the heme iron is the target of ODQ is confirmed by the finding that ODQ is not able to inhibit the stimulation of sGC induced by the iron-free protoporphyrin IX (Koesling and Friebe, 1999). A derivative of ODQ, NS 2028 (oxadiazolo[3,4-*d*]benz[*b*][1,4]oxazin-1-one), has been reported to have properties similar to those of ODQ (Olesen *et al.*, 1998).

YC-1, A NON-NO ACTIVATOR OF SOLUBLE GUANYLYL CYCLASE

With YC-1, a non-NO activator of sGC with allosteric effects on the NO-induced activation has been identified. The compound YC-1, a benzylindazol derivative, was first described as an inhibitor of platelet aggregation that causes an increase in the intracellular cGMP concentration (Wu *et al.*, 1995). YC-1 was shown to stimulate purified sGC about 10-fold (Friebe *et al.*, 1996a; Mülsch *et al.*, 1997). Although independent of NO, the presence of the heme group was a prerequisite for YC-1 stimulation. YC-1 exerted dramatic effects on the NO-stimulated enzyme; it increased the maximal NO-induced catalytic rate by about 40% and potentiated the stimulatory effect of submaximally activating NO concentrations. The concentration–response curve of NO was shifted to the left by YC-1, indicating that YC-1 sensitized sGC toward NO. Stimulation of sGC induced by the NO-independent activator protoporphyrin IX was also potentiated by YC-1, clearly demonstrating that YC-1 has an effect on the maximal catalytic rate and an effect on the sensitivity toward ligands at the heme group. The latter is impressively demonstrated by the ability of YC-1 to turn the poor sGC activator CO into an effective stimulator (Friebe *et al.*, 1996a). The YC-1-induced increase in sensitivity toward NO is achieved by a decrease in the dissociation rate (Friebe *et al.*, 1998b). In the case of CO, YC-1 has been reported to increase its association and also to decrease its dissociation from the heme (Sharma *et al.*, 1999).

A direct YC-1–heme interaction is rather unlikely (Friebe and Koesling, 1998), as YC-1 neither changed the Soret absorption of basal nor affected NO-stimulated sGC, and YC-1 caused only a very small shift of the absorption maximum of the CO-stimulated enzyme. In addition, YC-1 was found to bind not only to the nonstimulated but also to the heme-depleted enzyme, suggesting an allosteric site on the enzyme. As mentioned earlier in the section on the catalytic domain, YC-1 may bind to the region corresponding to the forskolin-binding region in the ACs, thereby increasing catalytic rate and decreasing the dissociation of NO.

In addition to the effects on the purified enzyme, YC-1 effects have been demonstrated in a variety of cells and tissues. In vascular smooth muscle cells, YC-1 was reported to induce a concentration-dependent relaxation of endothelial-free rat aortic rings precontracted with phenylephrine and to increase cGMP levels (Mülsch *et al.*, 1997; Wegener and Nawrath, 1997). The synergistic effects of YC-1 and NO have been studied in intact platelets (Friebe *et al.*, 1998b). YC-1 in combination with NO or CO led to complete inhibition of platelet aggregation at concentrations that were ineffective when administered alone. The synergism of YC-1 and NO was emphasized by a drastic increase in intraplatelet cGMP levels. Although the application of either NO or YC-1 at maximally effective concentrations led to only an approximately 13-fold increase in the intracellular cGMP concentrations, both drugs together resulted in an over 1300-fold rise of the cGMP content. When using CO instead of

NO, similar results were obtained. CO alone did not have an effect on platelet aggregation and cGMP formation.

YC-1 was shown to inhibit cGMP-hydrolyzing phosphodiesterases in platelet cytosol (Friebe *et al.*, 1998b; Galle *et al.*, 1999). Thus, YC-1 obviously has dual effects on cGMP levels in platelets, as it increases cGMP formation through stimulation of sGC and prevents cGMP degradation through inhibition of phosphodiesterases, thereby explaining the exceptional increase in the cGMP concentration in platelets. However, even in the presence of the nonspecific inhibitor of phosphodiesterases IBMX, that is, under conditions in which the YC-1 effect on phosphodiesterases should be abolished, YC-1 led to a 10-fold increase in the maximally NO-stimulated sGC activity in platelets. With regard to the increase in the maximal NO-induced catalytic rate, the YC-1 effect in platelets is far more pronounced than that on the purified sGC. Consequently, there may be unknown factors or conditions in an intact cellular surrounding that make sGC more sensitive toward YC-1.

In conclusion, the effects of YC-1 on sGC suggest the existence of a so far unknown allosteric site on the enzyme that modulates the catalytic rate and the responsiveness toward heme ligands. Ligands to this allosteric site may represent a novel class of drugs that may exert vasodilatory, antiaggregatory, and possibly other yet unknown effects by sensitizing sGC toward its physiological activator NO. In contrast to the NO donors commonly used in the treatment of coronary heart disease, YC-1-like substances would exert their action mainly at the sites of endogenous NO production. In addition to the therapeutical implications, it is tempting to speculate about the existence of naturally occurring allosteric modulators of sGC that may alter the sensitivity of the enzyme toward NO. In the case of endogenously generated CO concentrations reaching relevant levels, sGC may be significantly stimulated by CO in the presence of such an endogenous modulator.
